Glossary

Competition Use or defense of a resource, such as a desirable growing site for a plant and a food source or shelter for an animal, by an individual that reduces the availability of the resource for another individual.

Competitive exclusion Extirpation or extinction of one species by another in a given area through competition for resources.

Exotic (nonindigenous) species A species that occurs in an area outside of its historically known range and that has

been introduced into a new habitat or ecosystem, either intentionally or accidentally.

Native (indigenous) species A species that occurs naturally in a given area.

Nonindigenous crops Crop plants that did not originate in the range where they are cultivated. Most or 99% of all crop species grown in the US are introduced or nonindigenous species and have been introduced intentionally.

Introduction

Thousands of species have been intentionally introduced to new regions for explicit agricultural purposes, such as the growing of crops and pest control. Yet many species are also accidentally introduced, and these biological “invaders” end up doing harm to the areas they invade. They can cause major economic losses in agriculture, forestry, and other segments of the world economy if crops or other products are destroyed. One recent study reported that more than 50,000 species that have been introduced into the US since Columbus’ time have resulted in approximately \$238 billion in damages annually (Pimentel *et al.*, 2000; Pimentel, 2011). In addition, introduced species often have substantial negative impacts on global ecological integrity; for example, the presence of an alien invader can result in the extinction of many native species.

It is difficult and complicated to estimate the full extent of the ecological damages to world agriculture caused by exotic species and the number of species extinctions they have caused, because only approximately 20% of the estimated 10–15 million species in the world have been described and cataloged. Nonetheless, about 400 of the 958 species on the Threatened or Endangered Species List in the US are considered at risk primarily because of competition and predation by nonindigenous species. Other species are continually threatened by hybridization with alien species or ecosystem changes caused by biological invaders. Estimation of the economic impacts of nonindigenous pests affecting world agriculture is also difficult; however, sufficient data are available to quantify some aspects of the economic impacts on agriculture. This article assesses the magnitude of environmental impacts and some of the economic costs associated with the diverse nonindigenous species that have invaded world agriculture.

Exotic Species Introductions in the United States

Most plant and vertebrate animal introductions in the US agriculture have been intentional, whereas most invertebrate

animal and microbe introductions have been accidental. In the recent past, the rate of and risk associated with exotic species introductions have increased enormously because the human population is growing so rapidly; this ever-increasing number of humans has substantially altered, and continues to alter, the global environment (Pimentel *et al.*, 2001; Pimentel, 2011). In addition, large numbers of people are traveling faster and farther and more goods and materials are being traded among nations all over the world (Bryan, 1996), so the opportunity for even more species introductions is on the rise.

Nonindigenous Plants

Introduced Crop Plants

Most alien plants now established in the US were introduced for food, fiber, or ornamental purposes. An estimated 5000 plant species have escaped these realms and now exist in US natural ecosystems. This number is substantial when compared with a total of about 18,000 species of native US plants.

Ornamental plants are the largest group of nonindigenous plants that have become established in nature. These plants include those found in cultivated gardens, such as purple loosestrife (*Lythrum salicaria*). Of the approximately 25,000 cultivated plant species, mostly ornamentals brought into Florida, more than 900 have become established in surrounding natural ecosystems (Simberloff *et al.*, 1997). More than 3000 plant species have been introduced into California. New York state also has a large percentage of introduced plant species: 1082 exotics versus 1940 native species.

In crop systems, including forage crops, an estimated 500 introduced plant species have become weed pests. Most of these were accidentally introduced with crop seeds, from ship ballast, or from various imported dead and live plant materials. Some of these accidentally introduced weeds, like yellow rocket (*Barbarea vulgaris*) and Canada thistle (*Cirsium arvense*), have become major weed pests in US gardens and commercial agriculture.

Most of the 5000 nonindigenous plants established in US natural ecosystems have displaced some native plant species. Alien grasses introduced as forage species have diminished the

health of natural ecosystem functions as a result of nutrient losses, changes in microclimates, altered vegetation succession, and increased incidence of fires. Nonindigenous weeds are spreading and invading approximately 700,000 ha of US wildlife habitat each year (Babbitt, 1998).

One of these weed pests is the European purple loosestrife, which was introduced in the early nineteenth century as an ornamental garden plant. It has been spreading at a rate of 115,000 ha per year and is changing the basic structure of most of the wetlands that it has invaded. The dominant, monotypic stands of purple loosestrife have reduced the biomass of 44 native plants and endangered the wildlife that depends on these native plants.

Economic Costs of Introduced Plants

In US agriculture, weeds cause a reduction of 12% in crop yields; in economic terms, that represents an approximate \$33 billion loss in crop production annually, based on the potential crop value of all US crops of more than \$267 billion per year. Using the estimate that about 73% of the weeds are nonindigenous, it follows that around \$24 billion of these crop losses are due to introduced weeds. In addition, approximately \$4 billion in herbicides are applied to US crops, of which about \$3 billion can be attributed to nonindigenous weed control.

US pastures provide about \$10 billion in forage crops annually, with total losses due to weeds estimated at nearly \$2 billion. Since about 45% of these weed species are nonindigenous, the author estimates that forage losses due to these weeds are close to \$1 billion each year.

Some introduced weeds are actually toxic to cattle and wild ungulates. For example, leafy spurge (*Euphorbia esula*) contains a toxic substance that, when eaten by cattle, acts as an irritant, emetic, and purgative and can cause dysentery and sometimes death. Some animals, after unpleasant experiences, learn to avoid eating the plant. If the vegetation on grazing land is composed of just 10–20% leafy spurge, the cattle will not graze there and the value of the land as forage is lost. Total losses resulting from the prevalence of this weed on western rangelands account for nearly \$110 million per year due to toxic

effects and reduced grazing by the cattle (this cost is included in the \$1 billion in losses mentioned earlier) (OTA, 1993).

Several nonindigenous thistles also replace desirable native plant species in pastures, rangelands, and forests and similarly reduce cattle grazing. According to the US Secretary of the Interior Babbitt (1998), ranchers spend about \$5 billion each year to control invasive nonindigenous weeds in pastures and rangelands; despite those expensive efforts, though, these weeds continue to spread.

Lawn, garden, and golf course management costs about \$36 billion per year. A significant proportion of these management costs is related to pest control. In addition to the high cost of this commercial pest control, it is estimated that about \$1.3 billion (included in the \$36 billion) is spent on outdoor residential weed, insect, and disease pest control each year. Given the high percentages of nonindigenous species, the author estimates that about \$500 million is spent on residential nonindigenous weed control, and an additional \$1 billion is invested in nonindigenous weed control on golf courses. Therefore, the total economic cost of introduced weeds on US cropland, pastureland, and other uses is about \$35 billion annually (Table 1).

Nonindigenous Vertebrates

Mammalian Introductions

Introduced mammal species include dogs, cats, horses, burros, cattle, sheep, pigs, goats, monkeys, and deer (Layne, 1997). Several of these animals escaped or were released into the wild, and many have become pests by either preying on native animals, grazing on vegetation, or intensifying soil erosion.

For example, goats (*Copra hircus*) introduced on San Clemente Island, California, are responsible for the extinction of eight endemic plant species and the endangerment of eight other native plant species on the island (Kurdila, 1995). Horses (*Equus caballus*) and burros (*Equus asinus*) released in the western US have reached populations of up to 50,000 animals. These animals graze heavily on native vegetation, allowing nonindigenous annuals to displace native perennials. Furthermore, burros inhabiting the northwestern US compete for the primary food sources of native bighorn sheep and

Table 1 Economic losses to biological pest invaders in agriculture in the US, UK, Australia, South Africa, India, and Brazil (in billions of dollars)

Pest invader	US ^a	UK	Australia	South Africa	India	Brazil	Total
Plant weeds	\$35.000	\$1.200	\$2.400	\$2.500	\$23.724	\$12.300	\$77.124
Mammals							
Rats	19.000	4.400	1.200	2.700	25.000	3.200	\$55.500
Other	1.310	1.200	5.580	—	—	—	\$8.090
Birds	2.100	0.270	—	—	—	—	\$2.370
Arthropods	15.000	0.840	1.000	1.700	10.200	4.600	\$33.340
Microbes							
Plant pathogens	23.500	1.700	2.700	2.900	21.400	18.300	\$70.500
Livestock diseases	14.000	—	0.021	1.000	—	—	\$15.021
Total	\$109.910	\$9.610	\$12.901	\$10.800	\$80.324	\$38.400	\$261.945

^aIncludes pest control costs for lawns, gardens, and golf courses. See text for details.

See Table 1 of Chapter 17 of *Invasive Species* book for livestock disease figure — The author has added the US column and bottom row of total — also see Conclusions. For the final costs for US biological pest invaders — see *Microbe Introduction in Agriculture*.

seed-eating birds, thereby reducing the abundance of these native animals (Kurdila, 1995).

Overall, large populations of feral horses and burros are costly in terms of lost forage for livestock and wildlife. Based on a minimum of \$10 per animal-unit-month (AUM) per hectare, and assuming 10 ha of pasture per animal per year, these large animals exact damage of at least \$5 million per year. This cost does not include the extensive environmental damage to ecosystems, which can be up to 10 times this amount when increased soil erosion and the reduction of native plants and associated native animals are considered.

Pigs (*Sus scrofa*), which are native to Eurasia and North Africa, have been introduced into some US parks (like the California coastal prairie) for hunting, and have substantially changed the vegetation in those places. Feral pigs are also a serious problem for US agriculture. In Hawaii, more than 80% of the soil is bare in regions inhabited by pigs (Kurdila, 1995). This disturbance allows annual plants to invade the overturned soil and intensifies soil erosion. Pig control per park in Hawaii, with about 1500 pigs per park, costs about \$150,000 each year (based on \$100 spent per pig for control). Assuming that the three parks in Hawaii have similar pig control problems, the total is \$450,000 per year just in Hawaii (Zuniga, personal communication).

Pigs also have become a serious problem in Florida, where the feral pig population has risen to more than 500,000. In a few cases these invaders are beneficial – for example, pigs serve as a food source for the endangered Florida panther (Layne, 1997). For the most part, though, in Florida and elsewhere, pigs damage hay, grain, peanut, soybean, cotton, and various vegetable crops. Pigs also damage fences, livestock watering devices, ponds, and young livestock. In addition, they transmit and are reservoirs for serious diseases that affect both humans and livestock, like brucellosis, pseudobrucellosis, and trichinosis.

Nationwide, there are an estimated 4 million feral pigs (Pimentel *et al.*, 2000). Control costs for feral pigs range from \$36 per pig for poison control to \$140 per pig for hunting with dogs. Estimated damages are at least \$300 per pig per year. Assuming that 4 million feral pigs inhabit the US, the yearly cost is about \$800 million per year. This is a conservative estimate because pigs cause significant environmental damage that is not easily translated into dollar values.

In addition to large animals like horses and pigs, many small mammals have been introduced both accidentally and intentionally into the US. Some examples of these species are the European (black or tree) rat (*Rattus rattus*), Asiatic (Norway or brown) rat (*Rattus norvegicus*), house mouse (*Mus musculus*), nutria (*Myocaster coypus*), European rabbit (*Oryctolagus cuniculus*), cat (*Felis cattus*), and dog (*Canis familiaris*) (Layne, 1997).

Some rodents have become serious pests on farms, in industries, and in homes (Layne, 1997). On farms, rats and mice are particularly abundant and destructive. On poultry farms there is approximately one rat for every five chickens (Pimentel, 2011). Assuming this ratio, the total rat population on US poultry farms may easily number more than 1.4 billion. Even with a decline in the rat population since these observations were made, the author estimates that the number of rats on poultry and other farms is still approximately 1 billion.

Given an estimated 1 rat per person, there are an estimated 250 million rats in US urban and suburban areas. All told, there is a total of around 1.25 billion rats in the US.

Various studies report that an individual rat consumes or destroys from 210 to 740 kg of grain each year. If it is conservatively assumed that each rat consumes or destroys grain and other materials valued at \$15 per year, then the total cost of destruction by rats in the US is more than \$19 billion per year. In addition, rats cause fires by gnawing electric wires, pollute foodstuffs, and act as major vectors in the transmission of several diseases, including salmonellosis and leptospirosis, and to a lesser degree plague and murine typhus.

The Indian mongoose (*Herpestes auropunctatus*) was first introduced into Jamaica in 1872 for the biological control of rats in sugarcane plantations. It was soon introduced to Puerto Rico, other West Indian Islands, and Hawaii. The mongoose was effective in reducing the Asiatic rat population in some areas, but with reduced competition the European rat returned to being a major pest in sugarcane fields. Moreover, the mongoose preyed heavily on ground-nesting birds and subsequently reduced their numbers. It also preyed on amphibians and reptiles that were beneficial to biological pest control, resulting in a minimum of 7–12 extinctions in Puerto Rico and other islands of the West Indies. In addition, the mongoose emerged as the major vector and reservoir of rabies and leptospirosis in Puerto Rico and other islands. Based on public health effects, poultry losses, extinctions of amphibians and reptiles, and the elimination of many native birds, we estimate that the mongoose causes approximately \$50 million in damages each year in Puerto Rico and the Hawaiian Islands (Pimentel, 2011; Zuniga, personal communication).

Finally, most dogs introduced into the US have been domesticated, although some have escaped into the wild. Some of these feral dogs run in packs and kill deer, rabbits, and domestic cattle, sheep, and goats. It is estimated that feral dog packs in Texas cause more than \$5 million in livestock losses each year. Dog packs have also become a serious problem in Florida (Layne, 1997). Assuming \$5 million in damages for the other 47 continental states, total losses in livestock kills per year would be approximately \$10 million per year.

Exotic Birds

Of the 97 bird species introduced into the US, only 5% are considered beneficial; a majority (56%) are pests (Temple, 1992). Several nonindigenous bird species, including chickens and pigeons, were introduced into the US for agricultural purposes.

The common myna (*Acridotheres tristis*), introduced into Hawaii for biological control, helped control pest cutworms and armyworms in sugarcane. However, it became the major disperser of seeds of the introduced pest-weed *Lantana camara*. To cope with the weed problem, Hawaii was forced to introduce insect biocontrol agents for the weed (Kurdila, 1995).

The English or house sparrow (*Passer domesticus*) was introduced into the US intentionally in 1853 to control the canker worm. By 1900, the birds themselves were considered pests because they damage plants around homes and public buildings and consume wheat, green corn, and the buds of fruit trees. About 70% of the house sparrow's diet consists of grains (the introduced alfalfa weevil accounts for the other

30%). Furthermore, English sparrows harass robins, Baltimore orioles, yellow-billed cuckoos, and black-billed cuckoos. They also displace bluebirds, wrens, purple martins, and cliff swallows from their nest sites, and are associated with the spread of about 29 diseases that affect both humans and domestic livestock.

Similarly, European starlings (*Sturnus vulgaris*) are serious pests and are estimated to occur at densities of more than 1 per hectare in agricultural regions. They are capable of destroying approximately \$2000 worth of cherries per hectare. In grain fields, starlings consume about \$6 worth of grain per hectare. Therefore, assuming approximately \$5 per hectare for all damages to agriculture crop production in the US, the total economic loss due to starlings would total approximately \$800 million per year. In addition to these economic damages, starlings also have some negative environmental impacts. For example, starlings are aggressive and have displaced numerous native bird species, which can disrupt precariously balanced ecosystems. Starlings also have been implicated in the transmission of 25 diseases, including parrot fever and other diseases in humans and livestock.

The domestic pigeon (*Columba livia*) has been introduced for agricultural production and it has invaded most cities of the world, including US cities. Pigeons are considered a nuisance because they foul buildings, statues, cars, and sometimes pedestrians with their droppings, and because they feed on agricultural grain. Each pigeon consumes an average of 15 kg of grain per year (Smith, 1992). The economic impacts caused by fouling are estimated to be at least \$9 per pigeon per year (based on \$9 in control costs per pigeon). Assuming there is 1 pigeon per hectare in urban areas or approximately 0.5 pigeon per person in urban areas, common pigeons cause at least \$2.2 billion in damages each year. This estimate does not take into consideration pigeons' role as reservoirs for greater than 50 serious human and livestock diseases, including parrot fever, ornithosis, histoplasmosis, and encephalitis.

Thus, if we assume \$800 million per year in economic losses from starlings, \$2 billion per year from pigeons, and \$200 million for house sparrows and other birds, the damages from nonindigenous pest birds are estimated to be \$3 billion per year.

Nonindigenous Amphibians and Reptiles

The cane toad (*Bufo marinus*) and bull frog (*Rana catesbeiana*) were introduced into Florida, Puerto Rico, Hawaii, and other warm regions, in some cases for the biological control of pest insects. However, the cane toad, with its toxic skin glands, has proved lethal to birds, dogs, cats, and other mammals.

Nonindigenous Invertebrates and Microbes

Approximately 4600 arthropod species (2600 species in Hawaii and more than 2000 in the continental US) have been introduced into the US. Eleven earthworm species and nearly 100 aquatic invertebrate species also have been introduced (OTA, 1993). More than 95% of these introductions were accidental – many invertebrate species gained entrance *via* plant introductions, in soil, or in water ballast from ships.

Insects and Mites

Approximately 1000 nonindigenous insect and mite species are pests in crops, stored-food products, and structures. Hawaii has about 5200 identified native insect species, and an additional 2600 introduced insect species (Howarth, 1990). Introduced insects account for 98% of the pest insects in that state. In addition to Florida's 11,500 indigenous insect species, 949 immigrant species have invaded the state (42 species were introduced for biological control). In California, the 600 introduced species are responsible for 67% of all crop losses. Some of the California pests include the cottony cushion scale (*Icerya purchasi*) and alfalfa weevil (*Hypera postica*).

Each year pest insects destroy about 13% of potential crop production at a cost of about \$33 billion in US crops. Considering that about 40% of the pests were introduced, we estimate that these alien pests cause about \$13 billion in crop losses each year. In addition, about \$1.2 billion in pesticides are applied for all insect control each year. The portion applied against introduced pest insects costs approximately \$0.5 billion. Therefore, the total cost for introduced nonindigenous insect pests is approximately \$13.9 billion annually.

Lawn, garden, and golf course management activities cost about \$36 billion annually. More than \$3 billion per year is related to the expenses of pest control. Assuming the presence of 40% nonindigenous insect pests, the author estimates the control costs in lawns, gardens, and golf courses to be about \$1.5 billion each year.

Other introduced insect species have become pests of livestock and wildlife. For example, the imported red fire ant (*Solenopsis invicta*) kills poultry chicks, lizards, snakes, and ground-nesting birds. In some areas fire ants are extremely abundant, with as many as 367 nests per hectare. The estimated damage to livestock, wildlife, and public health caused by fire ants in Texas is estimated to be \$300 million. An additional \$200 million per year is invested in controlling these ants. Assuming equal damages in other such infested southern states, the fire ant damages total approximately \$2 billion per year.

Nonindigenous Earthworms

There are approximately 70 native US earthworm species. In disturbed habitats, 11 species of introduced earthworms have reduced the numbers of some of the native species. Although detailed data are not available concerning impacts of nonindigenous earthworms on US earthworm species and soil quality, earthworms are generally beneficial to soil productivity and formation in agriculture.

Microbe Introductions in Agriculture

Although some microbes were intentionally introduced into the US for wine and cheese making, most were accidentally introduced and some have become serious pests. The number of microbe species introduced into the US cannot be estimated because several thousand species can exist in a single gram of soil. Only a small fraction of all of these species have been identified.

More than 100 species of microbes have been intentionally introduced for processing wine, beer, cheese, and other foods. In addition, about 50 microbes have been introduced

for the biological control of pest insects. A strain of *Bacillus thuringiensis* (BT) was introduced and has been used extensively to control pest caterpillars. Other strains of BT have been developed to control beetles and mosquitoes.

An estimated 121 species of microbes, mostly introduced inadvertently in seeds and other parts of host plants, have become major crop pests in the US. US crop losses to all plant pathogens total approximately 12% of crops planted, a loss of \$33 billion per year. Approximately 65% of these crop losses – an estimated \$21 billion per year – are attributable to nonindigenous plant pathogens. In addition, \$0.72 billion is spent annually on fungicides to control plant pathogens; approximately \$0.5 billion of this goes toward the control of nonindigenous plant pathogens.

As mentioned earlier, lawn, garden, and golf course management activities have an annual cost of about \$36 billion; most of this is spent on pest control. Assuming that about \$3 billion of management costs are related to plant pathogen control and 65% of the pests are nonindigenous pathogens, we estimate the costs caused by introduced plant pathogens in lawns, gardens, and golf courses to be \$2 billion each year. Therefore, the damages caused by nonindigenous pathogens and the attempts to control them total about \$22.5 billion annually.

When all of the foregoing economic costs in crop and pastureland losses and for pest control for nonindigenous weeds, mammals, birds, insects, livestock pathogens, and plant pathogens are combined, the annual total is approximately \$109.91 billion (Table 1) to the US economy.

Exotic Species Introductions in the United Kingdom

Nonindigenous Plants

There are a total of 26,000 introduced plant species in the UK. An estimated 25,000 species are established in UK botanical gardens alone, 14,000 species are cultured as commercial horticultural crops, and there are 6000 species of noncultivated aliens. There are 1169 species of exotic plants known to be established in natural ecosystems. The native flora of the UK numbers only 1515 species (Crawley *et al.*, 1996).

Most of the alien plants occur in relatively few types of habitats. More than 80% of the alien species are present in waste ground areas, urban sites, roadway sides, and agricultural habitats. An estimated 63% of the alien plants occur in hedges and scrub areas; croplands and gardens harbor about 43% of the alien species (Crawley *et al.*, 1996). Finally, about 40% of alien species occur in rock walls and woodlands. It is interesting that plant communities like grazed, mesic grasslands and native *Pinus sylvestris* woodlands contain no alien plant species.

In UK agriculture, weeds cause an average reduction of about 10% in crop yields; however, this loss can be as high as 32% in some crops. In economic terms, about \$2.8 billion in potential crop production is annually lost due to weed infestations. Given the estimate that about 43% of the weeds are alien, it follows that \$1.2 billion of the crop losses are due to introduced weeds (Table 1).

Nonindigenous Vertebrates

Introduced Mammals

The total number of mammalian species in the UK is 54; 17 of these are alien species. The mammal introductions include domestic animals like dogs, cats, cattle, horses, sheep, and pigs, as well as other nondomesticated mammals. Some of the species that were intentionally or accidentally introduced into the UK include the gray squirrel (*Sciurus carolinensis*), European rabbit, North American mink (*Mustela vison*), brown rat, and black rat (Lever, 1994). All of these animals, except for cattle and horses, have escaped into the wild and are now well established.

In the UK, rodents are serious pests on farms, in industries, and in homes. The estimated number of rats are estimated at five per person (based on the rat-to-person ratio in the US), including rats on farms (Pimentel *et al.*, 2000). Thus the total number of rats is 295 million. Using the same value of \$15 for food and other goods damaged per rat, the cost of rats in the UK is about \$4.4 billion annually.

The European rabbit is also abundant in the UK, with densities in some areas of up to 30 rabbits per hectare. Assuming approximately 10 rabbits per hectare on the 7 million ha of cropland in the UK with an estimated \$11 damage per rabbit, the total annual economic damages from European rabbits are \$800 million per year. They are reported to reduce wheat production by about 5%–8%, and to reduce forage production for livestock by about 20%. With 11 million ha of pasture for livestock, we estimate these losses to be \$400 million per year. Thus, the total damage from the European rabbit in the UK is \$1.2 billion per year.

Introduced Birds

Out of the 542 bird species in the UK, 47 are alien species. Some of the introduced species include the Canada goose (*Branta canadensis*) and the little owl (*Athene noctua*). Only one of the 47 introduced bird species is currently causing major ecological or economic problems – the common pigeon. This bird does invade agriculture, but is most common in cities and towns (Lever, 1994). Pigeons are a particularly serious problem for reasons discussed earlier, namely, the pollution of city surfaces with their droppings and their consumption of grain in agriculture.

Assuming there is 1 pigeon per hectare, or 0.5 pigeon per person in urban areas (as in the US), then there are approximately 30 million pigeons in the UK. The estimated damage that a pigeon causes is a minimum of \$9 per year to crops and structures in cities and towns (Pimentel *et al.*, 2000). Therefore, pigeon damages are estimated to be at least \$270 million per year. This does not include the role of pigeons as reservoirs for greater than 50 human and livestock diseases, including parrot fever, ornithosis, histoplasmosis, and encephalitis. Pigeons are also responsible for transmission of at least three diseases to UK poultry, including Newcastle disease.

Nonindigenous Invertebrates and Microbes

Introduced Arthropods

There are approximately 23,000 native species and 1700 introduced species of arthropods in the UK. An estimated

1500 species are of economic importance; about 169 alien species are considered pests. An estimated 30% of the crop losses in the UK are associated with the introduced arthropod pests, as compared with about 40% in the US (Pimentel *et al.*, 2000).

Arthropods damage or destroy approximately \$2.8 billion in crops in the UK each year, based on the average of 10% crop losses per year. With about 30% of these losses due to introduced arthropods, they cause an economic loss of about \$840 million per year.

Introduced Crop Plant Pathogens

An estimated 74% of the plant pathogens in the UK were introduced when seeds and other crop parts were brought into the country for agriculture. Approximately \$8 billion is lost to all pests in crop production; about 8% of total potential production is lost to plant pathogens at a cost of about \$2.3 billion per year. If 74% of these crop losses are due to introduced plant pathogens, then about \$1.7 billion per year is associated with introduced microbes in crops.

Exotic Species Introductions in Australia

Nonindigenous Plants

There are approximately 20,000 vascular plant species in Australia (Pimentel, in press), including an estimated 1952 alien species. The rate of alien species introductions into Victoria, Australia, alone has been five to six species per year during the past century. Many of these species have become weeds and have invaded a wide range of environments. The invasive plants are a serious problem in both agricultural and wild ecosystems, where they disrupt key natural ecosystems, alter fire regimes, and reduce the resources for native animals. An estimated 60% of the weed species in crops in Australia are alien (based on a survey of major weeds in cereal crops).

The introduced blackberry (*Rubus proceus*) alone causes \$77 million worth of damages to crop production each year. The indirect and direct losses due to all weeds in pastures are estimated to be \$970 million per year. Weeds are estimated to cause about \$4 billion in total damages in crops and pastures. Therefore, invasive plants cause approximately \$2.4 billion per year in losses to agriculture (Table 1).

Nonindigenous Vertebrates

Introduced Mammals

There are presently 20 introduced mammals in Australia, including the European rabbit, hares (*Lepus europaeus*), water buffaloes (*Bubalis bubalis arnee*), cats, dogs, foxes (*Vulpes vulpes*), sheep, goats, cattle, horses, camels (*Camelus dromedarius*), pigs, and donkeys. In comparison, the number of native mammals is 227. The populations of some of these introduced mammals in the Northern Territory are quite high: buffaloes, 340,000; horses, up to 300,000; donkeys, up to 140,000; and camels, up to 30,000. The populations of these herbivores are much too high, but the costs of implementing a control program are also very high. For example, the cost of controlling buffalo is nearly \$30 per animal.

The herbivorous animals significantly reduce the vegetative cover by overgrazing and this intensifies soil erosion and encourages annual plants and inedible shrubs in pastures (Lever, 1994). Surprisingly, the most serious pest herbivorous mammal in Australia is not one of these large-hoofed herbivores, but rather the European rabbit. In Tasmania, the rabbit population in 1952 reached a density of up to 250 rabbits per hectare. The total number of rabbits in Australia ranges from 200 to 300 million. Approximately 15 rabbits consume the equivalent pasture forage of one sheep (Emmerson and McCulloch, 1994). The impact of rabbits on sheep production per year is estimated to be \$110 million, including reduced sheep production and rabbit control costs. If we assume a conservative estimate of only 0.5 rabbit per hectare for cropland and pastureland and also assume that each rabbit causes a minimum of \$5 damage, then on the 465 million ha of Australian cropland and pastureland, rabbits are causing at least \$1.2 billion per year in damages.

Feral pigs are also a serious problem in Australia, as they damage fences and spread animal diseases, including tuberculosis, brucellosis, rabies, and foot-and-mouth disease (Lever, 1994). The number of feral pigs ranges from 4 to 20 million. These pigs damage crops, kill lambs, and damage the natural environment; they are estimated to cause at least \$80 million per year in damages (Emmerson and McCulloch, 1994).

The house mouse damages crops, houses, farm machinery, and livestock production. Estimates for these annual losses range from \$50 to \$100 million per year. Far more serious than the house mouse, though, are the invading brown and black rats. In the US, there are 4.6 rats per person (Pimentel *et al.*, 2000). Assuming the same number of rats per person in Australia and that each rat causes \$15 of damage, then for a human population of 18 million, rats are causing approximately \$1.2 billion per year in damages in Australia.

Introduced pet cats and feral cats are also a serious problem, especially for native bird, mammal, and amphibian populations. There are an estimated 18 million feral cats in Australia and each cat is estimated to kill 8 birds per year. Assuming that 144 million birds per year are killed, and that each bird has a value of \$30, then damages from cats alone reach about \$4.3 billion per year.

Introduced Birds

Australia has 850 bird species, of which about 70 are alien species. Most of the introductions have been intentional, including the English starling, English house sparrow, and common pigeon. These birds are often restricted to cities and towns. Pigeons cause similar problems in Australia as they do elsewhere.

Introduced Reptiles and Amphibians

There are about 700 species of reptiles and amphibians in Australia, but only 2 of them are nonindigenous. One of these introduced amphibians, the cane toad (*B. marinus*), was introduced as a biological control agent for insect pests in sugarcane fields. Unfortunately, the toad has become a pest itself because it is poisonous to dogs, cats, and other mammals that attack it.

Nonindigenous Invertebrates

Introduced Arthropods

There are an estimated 108,000 arthropod species in Australia, with 54,000 species of native and nonnative insects and mites and 10,000 mollusk species. Crop losses due to insects and mites are estimated at 10.7% of Australia's gross potential production of \$22 billion per year. An estimated 36% of the pest arthropods in Australia are alien species. Based on arthropod-caused crop losses of about \$2.4 billion per year, the exotic pests account for losses of \$860 million per year. In addition, three exotic insects and mites cause \$228 million per year in damages to the wool industry alone. Thus, we estimate that exotic insect and mite species in Australia cause losses of at least \$1 billion per year.

Introduced Crop Plant Pathogens

If the total potential crop production in Australia is \$22 billion per year and about 15.2% of crop losses are due to plant pathogens, the economic costs of these pathogens total about \$3.3 billion per year. Because a large number of plant pathogens are introduced with crop seeds and other plant parts, an estimated 82% of the plant pathogens in crops are believed to be alien species (based on plant pathogens in field crops). Therefore, Australia loses \$2.7 billion per year in crops from exotic plant pathogens.

Microbe Introductions Affecting Livestock

There are an estimated 44 exotic animal diseases that could infect livestock in Australia. One exotic livestock disease, sheep pox, costs the wool industry an estimated \$21 million per year (Pimentel, unpublished data).

Exotic Species Introductions in South Africa

Nonindigenous Plants

There are 24,000 plant species in South Africa, including an estimated 8750 alien species. Most of the alien species were introduced from South America and Australia and have in turn invaded a wide range of environments. A total of 273 species of introduced plants in South Africa are serious weeds in crops (Bromilow, 1995).

Reduced crop production due to all weeds is 16.6% of potential crop production and total \$3.7 billion per year in losses (total potential agricultural production is \$22 billion per year). Assuming that 67% of the weeds in crops are alien (Bromilow, 1995), then the total loss in crop production due to alien weeds is \$2.5 billion per year (Table 1).

Two of the most serious plants invading pasturelands include the shrub *L. camara* and the cactus plant *Opuntia ficus-indica*. In addition to these two weeds, there are approximately 800 alien weed species out of a total of 1604.

Nonindigenous Vertebrates

Introduced Mammals

There are 16 species of introduced mammals in South Africa, including the European rabbit, hares, water buffaloes, cats,

dogs, sheep, goats, cattle, horses, camels, pigs, and donkeys. The total number of mammal species in South Africa, including alien species, is 247. As in Australia, the herbivore populations in South Africa are much too high for the resources that are available, and they significantly reduce the vegetative cover by overgrazing. This intensifies soil erosion and encourages some annual plants, weeds, and inedible shrubs to take over the pasturelands (Pimentel *et al.*, 2001).

Feral pigs are also a serious problem; they damage fences and spread disease in South Africa much as they do in Australia. The estimated control cost per feral pig in the US is about \$100 (Pimentel *et al.*, 2000), about the same as in South Africa.

Rats are a serious problem in South African agriculture as well as in urban areas. There are an estimated 4.6 rats per person in South Africa (based on data from the US; Pimentel *et al.*, 2000), which has a human population of 39 million people. Thus, there are about 179 million rats in South Africa; each rat is assumed to cause \$15 in damages per year. From these estimates, losses from rat damage total \$2.7 billion per year.

Introduced Birds

Of the 725 bird species in South Africa, only eight are alien species. Some of the introduced species include the English starling, common pigeon, Indian myna, and English house sparrow. Only the starling and pigeon are currently causing economic problems, and their damage is restricted to cities and towns. The problems with starlings and sparrows are very similar to the negative effects that these birds have elsewhere; namely, they pollute structures with their droppings and cause agricultural losses by consuming grains and fruits. In addition, pigeons, starlings, and sparrows are known reservoirs and vectors of up to 50 different diseases of humans and livestock.

Nonindigenous Invertebrates and Microbes

Introduced Arthropods

An estimated 80,000 species of insects, 6000 species of spiders, and numerous other arthropod species exist in South Africa. About 20% of these are believed to be exotic. One of the most serious invaders is the Argentine ant (*Linepithema humile*), which causes major problems because it destroys native vegetation, including endangered plants. The same ant also negatively affects native ants and other species of arthropods by competing with them for limited resources.

Insect and mite pests in agriculture cause 16.7% or \$3.7 billion in losses of potential crop production each year. Because approximately 45% of the insect and mite pests are exotic, the economic losses to exotic pests are estimated to be \$1.7 billion per year.

Introduced Crop Plant Pathogens

Approximately 85% of the plant pathogens that attack crops in South Africa are nonnative species (based on an assessment of diseases of fruits and vegetables). Most of these pathogens were introduced with the introduction of crops into South Africa. In forests, around 69% of the pathogens are exotic. Plant pathogens in South Africa cause an estimated 15.6% or

\$3.4 billion per year loss of the potential crop production. Since 85% of the pathogens are exotic, crop losses to exotic species total \$2.9 billion per year.

Microbe Introductions Affecting Livestock

Several serious livestock diseases, including tuberculosis, brucellosis, East Coast fever, anthrax, and rinderpest, infect livestock and other animals in South Africa (Pimentel, unpublished data). Estimates suggest that these livestock diseases are causing losses of around \$1 billion per year (Table 1).

Exotic Species Introductions in India

Nonindigenous Plants

There are 45,000 plant species in India, and an estimated 18,000 of these are alien species (Saxena, 1991). Many of the alien species have become weeds and have invaded a wide range of environments. Several weed species have been introduced along with the introductions of new crops. Weeds are estimated to cause a 30% loss in potential crop production, which totals about \$54 billion per year. Assuming that 42% of the weeds in crop production are alien, the total cost associated with invading weeds is \$22.8 billion per year (Table 1).

L. camara, a shrub introduced from South America as an ornamental plant, is a major weed in India, and it has invaded most pasturelands (13.2 million ha). Lantana is toxic to cattle and the cost of controlling it is \$70 per hectare. Only about 4% of India's land area is in pasture, yet total damage per year from Lantana is \$924 million.

Nonindigenous Vertebrates

Introduced Mammals

There are approximately 30 species of nonnative mammals in India, including cats, dogs, sheep, goats, pigs, axis deer (*Axis axis*), house mice, and rats. The total number of mammal species in India, including alien species, totals 320 (Pimentel *et al.*, 2001). As in other countries, the introduced herbivorous animals significantly reduce the vegetative cover by overgrazing, resulting in intensified soil erosion and increased invasion of pastureland by inedible weeds and shrubs.

Rats number at least 2.5 billion in India, or about 2.7 rats per person (Pimentel *et al.*, 2001). They attack crops in the field and are estimated to reduce potential crop yields by about 2%. In addition, rats are especially serious pests of stored grain supplies. Various studies report that an individual rat consumes or destroys about 210 kg of grain per year in India, and up to 740 kg of grain per year in Pakistan. Rats are estimated to destroy about 12 million tons of grain per year in India (Pimentel, unpublished data), in addition to damaging other foods, goods, and structures. In India the author estimates that each rat causes at least \$10 of damage per year, and thus they are responsible for at least \$25 billion annually (Pimentel *et al.*, 2001). In addition, rats are major vectors of and carriers of 38 human and livestock diseases. An average of 250,000 people die each year from the plague in India.

Introduced Birds

The number of bird species in India is 1221, including migrants and vagrants. Introduced species number only four, and include the English house sparrow, common pigeon, black francolin, and Alexandrine parakeet. In neighboring Pakistan, sparrows reduce potential wheat yields by 170,000 tons at a cost of \$26 million per year (Pimentel, 2011). Based on these data, losses in India are calculated to be \$50 million per year. Also, the common pigeon is a problem in agriculture, as well as in cities and towns, where it consumes grains and fouls buildings, statues, cars, and the occasional unlucky pedestrian. Pigeons are also involved in the spread of about 50 diseases that affect humans and livestock.

Nonindigenous Invertebrates and Microbes

Introduced Mollusks

An estimated 1500 species of land mollusks exist in India; several of these are exotic. The giant African snail (*Achatina fulica*) destroys from 0.29 to 4.3 g of grain per day per snail from eight major crops.

Introduced Arthropods

There are more than 30,000 species of arthropods in India. An estimated 560 mite species and about 600 species of insects are crop pests. About 30% of the pest species are introduced arthropods, and as a group they reduce potential crop production by 18.7%. Based on total potential crop production in India of \$181 billion per year, crop losses to alien arthropods total \$10.2 billion per year.

Introduced Crop Plant Pathogens

Plant pathogens reduce potential crop production in India by approximately 16%, at a total cost of \$29 billion per year. There are approximately 30,000 species of plant pathogens in India, and about 74% of the major pathogens are exotic species (based on the major plant pathogens in vegetable crops). Thus, the total cost of invading plant pathogens to crops in India is about \$21.4 billion per year.

Microbe Introductions Affecting Livestock

Several major diseases of livestock cause significant losses in India, most significantly foot-and-mouth disease. During 8 months in 1996, nearly 50,000 cases were reported at an estimated cost of \$17,000 per year.

The combined cost of crop losses that can be attributed to nonindigenous plants, mammals, arthropods, and plant pathogens is \$80 billion. Thus the negative effect of exotic species on Indian agriculture rivals that found in the US.

Exotic Species Introductions in Brazil

Nonindigenous Plants

Of the 55,000 plant species in Brazil, an estimated 21.1%, or 11,605, are alien species. Many of the alien species have become weeds and invaded a range of environments. In crop production, alien species make up 75% of the weed species. Weeds are estimated to destroy about 13.4% of Brazil's

potential crop and pasture production, or about \$12.3 billion per year (Table 1).

Nonindigenous Vertebrates

Introduced Mammals

The number of introduced mammals in Brazil is estimated to be 30, including cats, dogs, sheep, goats, cattle, horses, pigs, and donkeys. The total number of mammal species in Brazil, including alien species, is 428.

On the outskirts of São Paulo in the community of Taboao de Sera, estimates suggest that there are 12,500 feral dogs and 4600 feral cats (Pimentel *et al.*, 2001). The feral dogs attack livestock and other animals. Feral cats are also a serious problem, as they destroy birds and other native animals in Brazil.

It is estimated that there are about 320 million rats in Brazil. Assuming that each rat causes \$10 in damages, the total cost of rats is estimated to be \$3.2 billion per year.

Introduced Birds

The number of native bird species in Brazil is 1635. Only three, the English house sparrow, common wax-bill (*Estrilda astrild*), and common pigeon, are introduced species. The sparrow and pigeon populations cause major ecological and/or economic problems. The common waxbill is not considered a serious problem because it feeds primarily on the introduced guinea grass (*Panicum maximum*) and does little damage to this fast-growing grass (Pimentel, unpublished data).

Nonindigenous Invertebrates and Microbes

Introduced Arthropods

Invertebrate species number more than 100,000 in Brazil; about 70,000 are arthropod species. About 14.4% of potential crop production is destroyed by insects and mites, and approximately 35% of these pests are exotic. The calculated loss of crops to exotic insects and mites is estimated to be \$4.6 billion per year.

Introduced Crop Plant Pathogens

There are an estimated 100,000 species of microbes in Brazil; around 75% of the microbes that attack crops are exotic. Like most countries, most of these plant pathogens were introduced via alien crop species. Plant pathogens are estimated to cause 13.5% in crop losses each year. If 75% of the plant pathogen species are exotic, estimated losses from alien species total \$18.3 billion per year.

Conclusions

With approximately 400,000 nonindigenous species in various nations worldwide, if even a small fraction of these invaders are harmful, significant agricultural problems can result. While nearly all of our crop and livestock species are nonindigenous and have proven essential to the viability of the world's agriculture and economy, exotic species invasions

do result in many negative financial effects. This article shows that the economic damages of these alien species to the agricultural economies of just six nations (including, in some cases, control costs) amount to approximately \$262 billion each year (see Table 1). If this figure is extrapolated to all nations based on costs per person, the total cost of exotic species to world agriculture would be about \$943 billion per year.

Precise economic data for some of the most ecologically damaging biological invaders are not available. Mammals, including horses, water buffaloes, and goats, have been responsible for reducing the productivity of pastures and rangelands, as well as the extinction of many plant species in various ecosystems. In other areas, feral pigs and feral dogs have had serious impacts on agriculture, but as of yet few data are available concerning these animals.

Most of the exotic species in the world have been introduced within the past 70 years. Accelerated international trade and travel, plus rapidly increasing human numbers, guarantee that the threat from nonindigenous species invasions is still growing. The true challenge lies not in assigning precise dollar values to exotic species losses but in preventing further biological introductions and the resultant damage to managed and natural ecosystems. Although policies and practices to prevent the accidental and intentional introduction of exotic species are improving, the world's nations are woefully short of allocating sufficient resources to the problem in proportion to the risks. Both natural and managed ecosystems need to be protected from additional costly damages resulting from introduced species.

Glossary

Alleles Variants of nucleotides within the genome that cause changes in a given protein.

Crop genetic diversity: The diversity of the sets of genes carried by different individuals within a crop species. It occurs in the form of nucleotide variation within the genome.

Genetic diversity The diversity of the sets of genes carried by different organisms. It occurs in the form of nucleotide variation within the genome. When this variation causes a change in a given protein, the variants are called alleles. Allelic variation occurs at various genetic loci or gene positions within a chromosome.

Genetic erosion The loss of genes from a gene pool attributed to the elimination of populations caused by factors such as the adoption of high-yielding varieties, farmers' increased integration into the market, land clearing, urbanization, and cultural change.

Genetic variation The allelic variation that occurs at various genetic loci or gene positions within a

chromosome. Genetically variable loci are termed polymorphic or are said to show polymorphism.

Landraces These have a complex nature; therefore, it is not possible to give an all-embracing definition. Landraces are the originally adapted but variable crop populations on which farmers based their selections. They are geographically or ecologically distinctive populations which are conspicuously diverse in their genetic composition both between populations and within them. They have certain genetic integrity and are recognizable morphologically; farmers have names for them and different landraces are understood to differ in adaptation to soil type, time of seeding, date of maturity, height, nutritive value, use, and other properties.

Loci Gene positions within a chromosome. Allelic variation occurs at various genetic loci.

Spatial and/or temporal patterns of genetic

Variation The systematic changes in the alleles occurring at specific loci along spatial and/or temporal dimensions.

Introduction

During the past 200 years, and in a more accelerated way since 1960, the pattern of crop genetic diversity in the fields of the developing world has changed fundamentally. The germplasm that dominates the area planted with major cereals has shifted from the locally adapted populations that farmers historically selected from seed they saved—often called “landraces”—to the more widely adapted seed types produced by scientific plant breeding programs and purchased by farmers—often called “modern varieties.” These yield-enhancing seed types enabled the intensification of agriculture in areas of the world with high population densities. Initially, they diffused through the environments best suited for their production, spreading later—and unevenly—into less favored areas.

Economic growth, increasing incomes, and migration of labor from rural to urban areas lead to the commercialization of agriculture. Commercial crop production is characterized by the controlled application of water and other purchased inputs, such as fertilizer, fungicides, or pesticides to modern seed types. Sustained yield increases in commercial agriculture have depended not only on continued modifications in crop management practices but also on successive genetic improvements that are accomplished through recombining and exchanging diverse sources of germplasm. The spatial and temporal diversity among modern varieties in farmers' fields is determined in large part by the economic factors affecting their profitability and the performance of agricultural research institutions and seed industries.

In contrast, the genetic content and the geographical distribution of landrace populations are influenced more by natural selection pressures and the seed and crop management practices of traditional farming communities. Typically, it is not profitable to grow them with large amounts of purchased inputs since they are often grown principally for home consumption of food or feed and the size of their commercial market is limited. Seed markets for these varieties are generally local and rules for the exchange for seed, grain, and other products are more personal.

Today, the modernization of agriculture in the developing world is incomplete. In some areas with rain-fed, upland, or heterogeneous growing environments, landraces still dominate crop area or both modern varieties and landraces coexist. As the process of modernization continues, more farmers will be integrated into specialized product markets. Whereas others will work outside the farm and eventually leave it. Even then, local or export demand for certain quality attributes may provide market-based incentives for continued cultivation of landraces. In some places, there will be no alternative but to grow landraces for food since there may be no urban target for migration.

This article outlines some of the major implications of the modernization of agriculture for crop genetic diversity, focusing on the world's three principal cereals—rice, wheat, and maize. Wheat is a major tradable crop grown principally in temperate zones over a wide geographic area and often on relatively large, mechanized farms of industrialized countries.

The world's main wheat-producing regions are southern Russia and the Ukraine, the central plains of the United States and adjacent areas in Canada, northwest Europe, the Mediterranean basin, southwestern Australia, and, in the developing world, India, China, and Argentina. Rice is the most important food grain in the developing world. Almost all the world's rice is both produced and consumed on numerous small farms within Asia, with less than 5% of production entering trade. India, China, and Indonesia are the major producers. Maize is the world's most widely grown cereal in terms of growing environments and, after wheat, the most extensively traded cereal. Although virtually all the wheat and rice traded internationally are destined for human consumption, most of the maize is used to feed livestock. Maize is a very important part of the human diet in Africa, parts of Latin America, and Asia. Major maize-producing regions include the United States and parts of Europe, Mexico, Brazil, Argentina, South Africa, India, and China.

The next section summarizes the factors driving the intensification of agriculture. The section on *The Implications of Intensification for Crop Genetic Diversity* explains the implications of intensification for the patterns of genetic variation in the fields of the developing world. The section on *The Commercialization of Crop Production* discusses how commercialization affects these patterns and presents hypotheses concerning the future for crop genetic diversity.

The Intensification of Crop Production

What is the Intensification of Crop Production?

The intensification of agriculture refers to the increase in output per unit of land used in production, or land productivity. Population densities, expressed by the ratio of labor to land, explain much about where and under which conditions this process has occurred. The transition from low-yield, land-extensive cultivation systems to land-intensive, double- and triple-crop systems is only profitable in societies in which the supply of uncultivated land has been exhausted. The process of agricultural intensification has been observed in traditional and modern agricultural societies. The movement from forest and bush fallow systems of cultivation to annual and multi-crop cultivation systems, whereby plots of land are cultivated one or more times per year, has generally been influenced by increasing population densities in traditional societies. It is no accident that the modern seed-fertilizer revolution has been most successful in densely populated areas of the world, where traditional mechanisms for enhancing yields per unit area have been exhausted.

Intensive cultivation will also be observed in areas with lower population densities provided that soil conditions are suitable and markets are accessible. Intensification occurs in the less densely populated areas for two reasons: (i) Higher prices and elastic demand for output imply that the marginal utility of effort increases—hence, farmers in the region will begin cultivating larger areas, and (ii) higher returns to labor encourage migration into well-connected areas from neighboring regions with higher transport costs. Examples of regions with low population density but intensive,

market-oriented production are the central plains of Thailand and parts of South America's southern cone. If the conditions described are not present, labor and other costs associated with intensive agriculture are substantially higher than its incremental economic returns.

Intensification of land use and the adoption of yield-enhancing technologies have occurred in traditional and modern agricultural systems. In the case of Africa, [Pingali et al. \(1997\)](#) documented the movement from shifting cultivation to permanent agriculture with increases in population densities and improvements in market infrastructure. As land became scarce, traditional farming communities across sub-Saharan Africa began to extract increasingly higher levels of output from their land through investments in land improvements and soil fertility management. The intensification of traditional farming systems is a process that the more densely populated regions of Asia had been through several decades and in some cases centuries earlier. The application of modern scientific innovations in the form of high-yielding seeds and fertilizer allowed the extremely land-scarce regions of Asia to achieve levels of land productivity that were not possible through the exclusive reliance on traditional systems of farmer innovation.

Seed Technical Change: Traditional and Modern

The genetic evolution of cultivated crops is closely interwoven with the evolution of human civilization and crop husbandry. The recognition of wild species of cereal crops was first accomplished by primitive societies of hunters and gatherers, who harvested them for food. The domestication of wild species occurred when societies of shifting cultivators first began to cultivate food crops. Sedentary or permanent agricultural systems led to the emergence of ancestors of modern-day landraces of cereal crops. Although landraces have evolved over thousands of years under farmer management of natural selection, varieties have been bred by plant breeding programs for about 100 years. The first high-yielding maize hybrids were developed about 50 years ago. The high-yielding varieties of rice and wheat with semidwarf stature were developed less than 50 years ago and have been successfully adopted only in intensive agricultural production systems. Modern cereal cultivars have developed through three main phases of selection: (i) subconscious selection by the earlier food growers in the process of harvesting and planting, (ii) deliberate selection among variable material by farmers living in settlements and communities, and (iii) purposeful selection by professional breeders using scientific methods.

The main attainment of the first phase was to make the crop more suitable for planting and harvest by humans, threshing or shelling, and consumption. Higher germination rates, more uniform growing periods, resistance to shattering, and palatability were some of the achievements of this effort. In the second phase, many farmers exerted pressures continuously in numerous directions, resulting in variable populations that were adapted to local growing conditions and consumption preferences. These are broadly known as landraces. During the third phase, fields of cereals have become more uniform in plant types with less spontaneous gene

exchange. Planned gene migration has increased, however, with the worldwide exchange of germplasm. The products of the third phase are loosely referred to as “modern varieties.”

The genetic changes embodied in seed can lead to change in the productivity of land (yield) both directly and indirectly, in combination with other inputs. A primary example of such technical change is the “green revolution.” A term which has been used in various contexts to symbolize various types of social and technical change, it is first said to have been used by a USAID administrator to describe the rapid movement through Asia of new wheat and rice varieties coupled with increased use of fertilizer and irrigation. Here, we use it to refer specifically to the widespread adoption of semidwarf rice and wheat varieties in the developing world during the late 1960s and early 1970s. When grown with increased levels of fertilizer and a controlled water supply, these varieties performed significantly better than the varieties they replaced. Initially, they spread rapidly throughout many of the irrigated zones of the developing world where rice and wheat cultivation was concentrated and where population densities were high. Later, more widely adapted descendants of these varieties spread gradually into less favorable environments, including rain-fed areas with relatively modest production potential. Their diffusion was faster in the plains and valleys, diminishing up the hillsides and in more heterogeneous environments. The term modern varieties is also used to refer more exclusively to semidwarf varieties of rice and wheat.

Conservationists who observed the popularity of the green revolution varieties expressed concern for the possible loss of valuable genetic resources and narrowing in the genetic stock that serves as the basis for crop improvement (Frankel, 1970; Harlan, 1992; Hawkes, 1983). In the next section, the implications of the intensification of agriculture for crop genetic diversity are outlined. First, crop genetic diversity is defined. Some historical perspective is then provided on the spatial and temporal distributions of genetic variation in rice, wheat, and maize. Current estimates of areas planted with modern and landrace varieties of these cereals are reported. Evidence on the genetic diversity of modern varieties and landraces follows.

The Implications of Intensification for Crop Genetic Diversity

Crop genetic diversity broadly defined refers to the genetic variation embodied in seed and expressed when challenged by the natural and human selection pressures that shape the environment in which it grows. In applied genetics, diversity refers to the variance among alternative forms of a gene (alleles) at individual gene positions on a chromosome (loci), among several loci, among individual plants in a population, or among populations (Brown *et al.*, 1990). Diversity can be measured by accessions of seed held in gene banks, lines or populations utilized in crop-breeding programs, or varieties cultivated by farmers (cultivars).

The relationship between precise quantitative measurements and what can be casually observed among the plants growing in a field, and between these measurements and what can be observed in other environments, is indirect. Crop genetic diversity cannot be literally or entirely observed at any

point in time; it can only be indicated with reference to a specific crop population and analytical perspective. To understand the implications of agricultural intensification to crop genetic diversity, it is first necessary to gain a spatial and temporal perspective of the variation in crop plants.

Current Spatial Patterns of Genetic Variation

The adoption of modern cereal varieties has been most widespread in land-scarce environments and/or in areas well connected to domestic and international markets. Even in these areas, the profitability of modern variety adoption has been conditioned by the potential productivity of the land under cultivation. For instance, while modern rice and wheat varieties spread rapidly through the irrigated environments, their adoption has been less spectacular in the less favorable environments—the drought-prone and high-temperature environments for wheat and the drought- and flood-prone environments for rice. Maize, as discussed later, has an even spottier record in terms of farmer adoption of modern varieties and hybrids. For all three cereals, traditional landraces continue to be cultivated in the less favorable production environments throughout the developing world.

Recent estimates of the areas planted with modern varieties and landraces are shown in Table 1. Based on data from a global wheat survey conducted by the Centro Internacional de Mejoramiento de Maíz y Trigo (CIMMYT) in 1997, approximately 80% of the wheat area in the developing world was sown to semidwarf varieties, with the remainder split almost equally between improved tall varieties and landraces or varieties with unknown ancestry. The relative importance of tall wheat varieties remains greater in the industrialized than in the developing countries, probably for reasons related to wheat-growing environment and management practices.

Most of the extensive area sown to wheat landraces is found in parts of Turkey, Iran, Afghanistan, and Ethiopia. Pockets of landrace diversity for special traits may also be found throughout the Mediterranean region (Morocco, Tunisia, Syria, Egypt, Cyprus, Portugal, Spain, and Italy) as well as Nepal, Outer Mongolia, and Tibet, although field research and data analysis would be needed to confirm these hypotheses. Work in Mexico, Guatemala, Honduras, Peru, and Bolivia indicates the presence of unique landrace varieties that were probably introduced by Spanish immigrants in the sixteenth century. No significant areas are believed to be sown to wheat landraces in the former Soviet Union or in Eastern Europe, despite the historical importance of these areas for major progenitors such as the so-called “Turkey” and “five” wheat. The loss of landrace populations in the former Soviet Union was no doubt a consequence of collective agriculture that was practiced in the region for several decades.

Approximately three-fourths of the rice area in Asia, which produces most of the world’s rice, is thought to be sown to semidwarf varieties. Semidwarf varieties dominate the irrigated rice ecosystems of Asia and cover substantial areas in the favorable rain-fed lowlands (M. Jackson and G. Khush, personal communication). In the more marginal rain-fed lowland environments, the deep-water environments, and the

upland rice environments, farmers continue to grow landraces adapted to those particular environmental niches. Although more accurate data concerning rice landraces in Asia are now being compiled at the International Rice Research Institute (IRRI), the most comprehensive data from a national-level sample survey conducted by the Department of Agricultural Extension in Bangladesh (1996–1997) suggests that although farmers in that country still grow large numbers of named varieties including landraces (more than 300), more than 20 modern varieties cover nearly 65% of the total rice area. In West Africa, semidwarf varieties cover essentially all the irrigated lowlands and one-third of the rain-fed lowlands, but landraces and other improved varieties appear to occupy most of the area in uplands, mangrove, and deep-water flooded areas. Particularly in the deep-water/floating rice environment near Mopti in Mali, Birnin Kebbi in Nigeria, and in northern Guinea are found *Oryza glaberrima* (African rice) and tall traditional *O. sativa* (Asian rice) cultivars. The West African Rice Development Association (WARDA) has recently developed hybrid crosses of *O. sativa* and *O. glaberrima* species. In East Africa, the area in Madagascar seems to be approximately evenly split between traditional and modern varieties. In Latin America, tall and landrace varieties cover most of the upland area, whereas few are found in the irrigated and rain-fed lowlands.

In the uplands of Asia, traditional varieties still dominate, with “pockets” of important diversity in the Bastar Plateau (Madhya Pradesh, eastern India), parts of northern Bangladesh and the Chittagong Hill Tracts in that country, northern states of Myanmar, almost all of Laos, and parts of Cambodia (M. Jackson and G. Khush, personal communication). Oka (1988) reported that the genetic diversity in landraces of Asian rice was most prevalent in the area extending over Assam, Bangladesh, Burma (now Myanmar), Thailand, Laos, and Yunnan, China. Although Oka also reported that diversity was relatively high in Indonesia, which lies outside the center of domestication, much of Indonesian ricelands are now planted with modern varieties.

Data from global maize surveys conducted by CIMMYT in 1992 and 1997 indicate that, relative to wheat and rice, far less of the maize area in the developing world is planted with maize types released by plant breeding programs. Hybrids appear to occupy an increasing proportion of the area planted with modern maize types, but in zones such as Latin America, most of the maize area is still planted with landraces.

At least some of the area listed under landraces is planted with populations that result from the genetic integration of modern varieties with landraces when farmers save seed or plant seed of different types in adjacent fields. Similarly, a substantial proportion of the maize area in sub-Saharan Africa is planted with advanced generations of improved varieties whose seed farmers could not afford to replace on a regular basis introgressed with landrace populations brought to the continent with the slave trade several centuries ago. Although there appears to be a high proportion of maize landraces grown in West Asia and North Africa, the total area in maize is limited in this region and many of these are likely of unknown origin. In the industrialized world, a negligible percentage of maize area is planted with either improved open-pollinated varieties or landraces. These are specialty maizes or “heirloom” varieties grown for fresh consumption, popcorns, or ornamental corns such as those marketed on holidays in the United States.

The data in Table 1 confirm that although much of the genetic variation in the world’s wheat and rice area is shaped today by the efforts of modern plant breeders, a substantial part of the genetic variation in the maize grown in the developing world remains in the hands of farmers, some of which are among the poorest in the world. In some zones of production, such as Turkey and Iran for wheat or parts of Latin America for maize, fairly large contiguous areas may be planted to landraces. Often, in regions of crop domestication and diversity, landraces persist “as patches and islands of farming systems” (Brush, 1995, p. 246). Harlan (1992, p. 147) invoked the term “microcenters of diversity” to describe “relatively small regions, 100–500 km across, in which may be

packed an astonishing variation" within extensive areas of apparent uniformity in parts of Turkey, the Caucasus, Iran, and Afghanistan. Oka (1988) called the Jeypore Tract in India a microcenter of diversity in Asian rice. Jackson (personal communication) refers to some of the upland rice areas of Asia as "pockets" of diversity.

The change in the crop genetic landscape from predominantly traditional to largely modern patterns of genetic variation occurred during the past 200 years and at an accelerated rate since the 1960s. Whether the change to modern varieties has resulted in a narrowing of genetic diversity remains largely unresolved for many reasons, which are discussed in the following sections and further in Smale (1998) and Wood and Lenné (1997).

Comparing Genetic Diversity in Landraces and Modern Varieties

A major problem in assessing whether genetic narrowing has occurred with the replacement of landraces by modern varieties is the magnitude of the sampling and measurement effort that would be required to test the hypothesis in a meaningful way. In most cases it would be impossible to locate reliable samples of the landraces originally grown in an area now planted with modern varieties since this process occurred over time and unevenly across environments.

In some sense, the genetic diversity of landraces and modern varieties is incomparable by definition since its structure is distinct for each. Hawkes (1983) wrote that landraces, which are mixtures of genotypes, "could not even be called varieties." He called the range of genetically different varieties available to breeders "the other kind of diversity" (pp. 100–101). Harlan (1992) described a landrace as "an integrated unit" of "component genotypes" that have adjusted to one another over the generations as well as to the local environment, both natural and man-made (p. 148). A field planted with a rice or wheat landrace may be viewed by a plant breeder as a mixture of several lines but viewed by the farmer as one single variety because of its recognizably distinct agronomic, processing, or consumption characteristics. Vaughan and Chang (1992) described traditional rice types that are mixtures or composites of morphologically distinguishable types grown together deliberately.

The breeding system of the crop plant also affects the structure of genetic variation. Landraces generally contain some heterozygous material, though the extent of segregation is considerably greater for open-pollinated than for self-pollinated species. Maize is a cross-pollinating species, and maize in Mexico is often cited as an example of deliberate manipulation of the composition of landraces by farmers. Landrace varieties of maize evolve continuously through the purposeful mixing of seed lots of the same varieties or introgression by farmers, as well as inadvertently when fields of maize planted with different varieties flower simultaneously. A single "race" or race complex, as understood by maize geneticists, contains numerous genetically distinct farmers' varieties.

The distinction between modern varieties and landraces can also be blurred for predominantly outcrossing crops such

as maize, making it difficult to determine which population is under study. Many small-scale, subsistence-oriented maize farmers promote hybridization between improved varieties and landraces by growing them together or in neighboring fields and producing what farmers in Mexico call "creolized" varieties. Also termed "rustication" or simply "adaptation," this process may enable improved varieties to fit better the need of local farmers.

These points imply that comparing counts of landraces and modern varieties as an index of genetic narrowing may not make sense. They also imply that even if reliable samples of the landraces originally cultivated in an area could be obtained, analyses comparing their genetic diversity might provide only part of the answer regarding genetic narrowing. Although the landrace in the farmers' field is a heterogeneous population of plants, it is derived from generations of selection by local farmers and is therefore likely to be local in adaptation. The plants of a modern variety are uniform but the diverse germplasm in the genetic background may enable them to adapt more widely. The diversity in a modern variety may not be expressed until challenged by the environment. On the other hand, the landrace may carry an allele that occurs rarely among modern varieties and is a potentially valuable source of genetic material not only for the farmer that grows it today but also for future generations of producers and consumers.

When did Genetic Narrowing Occur?

Another problem in assessing the relationship of modern varieties to genetic narrowing is the temporal point of reference. Porceddu *et al.* (1988) described two major stages of genetic narrowing in wheat during modern times. The first occurred in the nineteenth century when scientific plant breeding responded to the demand for new plant types. Farming systems emerged that were based on the intensive use of land and labor, livestock production, and the use of organic manure. Changes in cultivation methods favored genotypes that diverted large amounts of photosynthates into the ear and grain. Bell (1987) reports that the engineering innovations of the late nineteenth century led to the establishment of extensive wheat-growing areas in North America, Australia, and parts of South America. Mechanization of agriculture dictated uniformity in plant type.

According to Porceddu *et al.* (1988), a second stage of narrowing occurred in the twentieth century, when genes were introduced to produce major changes in plant type. Use of the dwarfing genes *Rht1* and *Rht2*, for example, conferred a positive genotype-by-environment interaction in which yield increases proved greater given a certain combination of soil moisture, soil fertility, and weed control. Varieties carrying these dwarfing genes were developed by N. Borlaug with the national breeding program in Mexico and later by the International Maize and Wheat Improvement Center (CIMMYT). They became known as the green revolution wheats.

Evenson and Gollin's (1997) summary of the history of rice breeding suggests a process of continual expansion and narrowing of the genetic pool. Organized breeding efforts probably date earlier than 1000 AD in China. Modern efforts

can be traced to the late nineteenth century in several parts of Asia. In temperate east Asia, the first significant advances were made by Japanese farmers and scientists when they developed relatively short-statured and fertilizer-responsive cultivars. Known as the *rono* varieties, these belonged to the *japonica* class of rice and were widely cultivated in Japan as early as the 1890s. During the Japanese occupation of Taiwan in the early part of the twentieth century, Japanese scientists sought to adapt these varieties to the more tropical conditions of Taiwan. At the same time, researchers in tropical Asia were seeking more productive varieties of rice from the *indica* and *javanica* classes of rice. After World War II, the United Nations Food and Agricultural Organization initiated a program to cross *indica* rice with *japonicas* as a means of increasing rice yields, culminating in the formation of the IRRI and the green revolution varieties of rice.

To Vaughan and Chang (1992), genetic narrowing in modern rice began early in this century. Development projects, population increases, and forest clearing in Asia were the primary causes of the loss of wild and cultivated rice landraces. In the Mekong Delta, the replacement of traditional deep-water rice by irrigated rice occurred with drainage and irrigation schemes that were introduced during the French colonial period.

Goodman (1995) reports that the major portion of the variability now found in maize developed before European contact (circa 1500), and several of the most widely grown races, including the commercially important Corn Belt dents, developed later. During the “corn show era” in the nineteenth century, U.S. farmers exhibited their open-pollinated varieties locally and emphasis was placed on uniformity and conformity to an “ideal type.” By the early 1950s, essentially all of the maize grown in the Corn Belt was double-cross hybrid. After the late 1950s, increasingly more farmers in the U.S. Corn Belt grew single-cross rather than double-cross hybrids. Because single-cross seed must be produced on an inbred line, this type of selection contributed to a marked loss of variability in U.S. breeding materials. According to Goodman, a countervailing influence during the past 25 years has been the emphasis by public researchers on development of improved maize populations.

Not all scientists agree about what constitutes genetic narrowing or precisely when such narrowing has occurred. For instance, in contradiction with Porceddu *et al.* (1988), Hawkes (1983) cites the introduction of *Rht1* and *Rht2* genes into Western wheat breeding lines as an example of how diversity has been broadened by scientific plant breeders. The Japanese line Norin 10 carried the dwarfing genes from the landrace Daruma, believed to be of Korean origin. Similarly, the efforts to increase rice yields by crossing *japonica* and *indica* classes of rice extended the gene pool accessible to rice breeders. As these examples suggest, in modern agriculture, today's broadening of the genetic pool in a plant breeding program may lead to a narrowing of the breadth of materials grown by farmers precisely because such innovations often produce varieties that are popular.

Trends in Genetic Diversity of Modern Varieties of Rice, Wheat, and Maize

Part of the concern for genetic narrowing is based on the perception that, with time, conventional plant breeding

practices inevitably restrict the genetic base of modern varieties. The evidence from studies on the parentage of modern varieties lends little support to the view (Witcombe, 1999). In an analysis of genealogies of 1709 modern rice varieties, Evenson and Gollin (1997) found that although a variety released in the 1960s had 3 landraces in its pedigree, recent releases have 25 or more. The complexity of rice pedigrees, in terms of parental combinations, geographical origin, and number of ancestors, has expanded over time. A similar pattern has been shown for about 800 wheat varieties released in the developing world since the 1960s (Smale, 1997). The average number of distinct landraces found in bread wheat pedigrees increased from approximately 20 in the mid-1960s to about 50 in 1990.

Skovmand and de Lacy (1999) analyzed the distance among coefficients of parentage for a historical set of CIMMYT wheat varieties during the past four decades. Their results show a rate of increase in genealogical diversity that is positive but decreases over time, with marked expansion in genealogies from 1950 to 1967 and gradual flattening through the 1990s. If progenitors were recycled and reused, the distance among them would decrease over time and the slope of the line would be negative.

Less evidence is available worldwide on trends in the pedigrees or ancestry of maize varieties than for rice and wheat, in part because this information is confidential in an increasingly privatized industry. Following the epidemic of corn blight in the U.S. crop in 1970, the National Research Council (1972) concluded that the genetic base of maize in the United States was sufficiently narrow to justify concern. Duveck (1984) found that during the 10 years following the 1970 epidemic, breeders had broadened their germplasm pools.

Molecular markers, like genealogies, can be used to construct indicators of the latent diversity in a set of crop populations. Using molecular markers, Donini *et al.* (2000) concluded that there is no objective evidence to support the assertion that modern plant breeding has reduced the genetic diversity of U.K. wheats since 1930. Recent molecular evidence for a set of CIMMYT wheats indicates that genetic distance has been maintained among major parents and popular varieties during the past 30 years (unpublished data). Since many of the varieties of spring bread wheat grown in the developing world have a combination of CIMMYT and locally bred materials in their ancestry (Heisey *et al.*, 1999), these data represent a lower bound on actual genetic diversity. Furthermore, the genetic diversity that is accessible to conventional plant breeders today includes not only spring bread wheat, of course, but also wheat types with different growing habits, close relatives, and wild grasses. Techniques of biotechnology may traverse the species barriers faced by conventional breeders.

The Commercialization of Crop Production

What is Commercialization of Crop Production?

Economic growth, urbanization, and the withdrawal of labor from the agricultural sector have led to the increasing

commercialization of agricultural systems. Subsistence-oriented monoculture food production systems give way to a diversified market-oriented production system. Agricultural commercialization means more than the marketing of agricultural output: It means that product choice and input use decisions are based on the principles of profit maximization. Commercial reorientation of agricultural production occurs for the primary staple cereals and for the so-called high-value cash crops. Commercialization of agricultural systems leads to greater market orientation of farm production; progressive substitution of nontraded inputs in favor of purchased inputs; and the gradual decline of integrated farming systems and their replacement by specialized enterprises for crop, livestock, poultry, and aquaculture products (Pingali, 1997).

On the demand side the process of agricultural commercialization is triggered by rapid income growth and the consequent diversification in food demand patterns. A slowdown in income-induced demand for rice and for coarse grains is accompanied by a shift of diets to bread and higher valued foods such as meat, fruit, and vegetables. These dietary transitions are induced by the growth in per capita income and by the rapid migration of population to urban areas. The need to provision the rapidly growing cities of the world also acts as an impetus for the transformation of food production systems.

On the supply side, growing factor scarcities contribute to the demise of subsistence agricultural systems. Although growing land and water scarcity can be compensated for with increasing scientific knowledge and farmer management, farmer time required for sustaining productivity and profitability of intensive food production systems will become increasingly scarce. The collapse of subsistence systems will come about because of the competing demands for farmers' time. Although the speed of the structural transformation differs substantially across countries they are all moving in the same direction.

Seed Industries

As the orientation of crop production shifts from subsistence toward commercial objectives, the locus of crop improvement and seed distribution moves from individual farmers toward an organized seed industry composed of specialized private and public organizations. In terms of an increased reliance on commercially produced seed, this has occurred substantially faster for maize than for rice and wheat. In a stylized depiction of the maize seed industries in developing countries, subsistence production is characterized by open-pollinated varieties improved through farmer selection and on-farm seed production with local seed markets governed by custom. In a fully commercial system, the predominant seed type is a hybrid that is purchased annually. Seed is traded globally and is a product of specialized research that is both privately and publicly funded. The exchange of seed and the genetic resources used to improve it are enabled and protected by strict forms of intellectual property rights.

For rice and wheat, which are self-pollinating crops, the incentives for privatization of research have not always been as strong as those for maize, although this depends on the

institutional and economic context. In industrialized countries, profound changes in science and in intellectual property protection during the past 20–30 years have been associated with a higher rate of investment in agriculture by the private sector than the public sector and a shift in the composition of private investment from agricultural machinery and processing into chemical research and plant breeding. Although privatization is greatest in the maize seed industry, it is also occurring in wheat to a lesser extent and particularly in Europe. There is very little private sector rice breeding anywhere in the world. Almost all the research on rice has been conducted by the public sector, and most of this has taken place in Asia. In the developing world, there is increasing privatization of the maize seed industry but rice and wheat remain primarily public.

In commercial systems of rice, wheat, and maize, recent changes in the structure of the seed industry are likely to have implications for the utilization of modern patterns of genetic variation. The global seed industry has integrated both vertically (within production processes) and horizontally (among production processes) into "life science" firms that combine seed, chemical, and pharmaceutical businesses. As part of this structural change, firms are engaging in strategies to ensure more exclusive proprietary rights, including, for the first time in history, patents on genetically modified organisms.

The implications of these changes for the exchange and utilization of the genetic resources that are used in breeding modern varieties are unknown. Efforts are under way to harmonize intellectual property regimes globally through international trade agreements, but differences between developed and developing countries, as well as among developing and developed countries, pose challenges. Small public plant breeding programs in developing countries are not on the same footing with respect to investments and legal clout as the life science conglomerates. The maize, wheat, and rice industries are likely to be affected in different ways given the nature of economic incentives associated with seed reproduction. Patents are only one type of intellectual property right; in addition to intellectual property rights, national seed regulatory systems will have a strong impact on farmers' access to seed and the conservation of plant genetic diversity.

The Implications of Commercialization for Crop Genetic Diversity

Agricultural commercialization influences the extent of crop genetic diversity in two ways: (i) through changes in land use patterns and (ii) through crop choice changes in the irrigated as well as the rain-fed environments. The organization and management of food production systems in both the irrigated and the rain-fed environments are affected by economic growth. The opportunity cost of family labor can be expected to increase equally in the high- and low-potential areas since the populations in both environments are responding to nonagricultural employment opportunities. The declining viability of subsistence production systems can also be expected to be similar. The movement from subsistence to market-oriented, rain-fed production could follow a general pattern: (i) the abandonment of highly drought-prone

environments, especially in areas where the opportunities for groundwater exploitation are limited; (ii) the shift from small subsistence farms to mechanized cultivation of large farms; and (iii) where dry season water supplies are available, increased areas under vegetables, feed grain and fodder crops, and other high-valued crops. Cereal crop production would continue to have a comparative advantage in the rain-fed environment, primarily because of the high cost of modifying the environment in order to make it suitable for noncereal crops. Low-input, low-yield cereal production systems, rice and maize, grown on consolidated holdings may emerge as the most viable option for the rain-fed environments. The irrigated environments, on the other hand, would shift from being predominantly under cereal monoculture to a highly diversified production system. The implications of these changes in crop choice on genetic diversity in the irrigated and rain-fed environments are discussed in the following sections.

Implications When Intensification has Occurred

In the irrigated rice and wheat production zones of the developing world, commercialization has had little impact on crop genetic diversity beyond that of agricultural intensification. Since the modern varieties grown there are varieties rather than hybrids, their seed is saved and spreads now, as in the past, from farmer to farmer. This will change if hybrids, or certain types of transgenic varieties that require annual seed purchase, are developed. It may also change if the demand for labor-saving technologies such as herbicides leads to the use of herbicide-tolerant varieties. These must be purchased annually to prevent the carryover of weed seed.

The effects of commercialization on maize crop genetic diversity, independent of those associated with agricultural intensification, are much more pronounced because of the historical importance of hybrids relative to improved, open-pollinated varieties. The distinctive biological properties of maize plants (in particular, their propensity for open pollination and their tendency to segregate) make it difficult for farmers to maintain the genetic purity of maize seed saved from their own harvest. Commercial maize growers are therefore dependent on reliable external sources of affordable seed in a way that growers of self-pollinated rice and wheat are not. The reliance on the seed industry will continue to grow for maize if farmer use of genetically engineered seed increases in importance in the future.

The survival of landrace diversity for cereal crops in the high-potential, irrigated environments would depend on farmer incentives for maintaining that diversity. To a large extent, farmer incentives to do so would depend on the market demand for the unique quality characteristics that are present in some of the landraces. The importance of Basmati rice in the irrigated production zones of India and Pakistan is an example of how market demand for quality can influence the survival of traditional varieties and landraces. Even where modern varieties are used exclusively, diversity within the plant has increased over time, as discussed previously, by the introduction of new gene pools through breeding.

Implications when Intensification has not Occurred

The areas of the developing world where modern varieties are not widely grown are typically marginal for production of the crop or are inadequately served by markets and infrastructure. In some areas, agricultural research has been unable to produce varieties demonstrating an obvious yield advantage or commercial seed systems have not had the incentive to do so because of the small size of the market or fluctuating effective demand.

As suggested previously, this may remain the case for sizeable portions of the developing world's maize area. The proportion of cultivated area that is irrigated is far less for maize than for rice and wheat, whereas the use of purchased inputs remains modest. Most of the farmers who grow maize in developing countries face difficult and variable maize production environments and cultivate it with the primary objective of meeting subsistence requirements. These farmers have little incentive to make investments in fertilizer, pesticides, and other modern means of coping with disease and weather since their traditional varieties do not respond as well to these as modern varieties. In many of these production zones, it is not easy to breed well-adapted materials and there are few profits to be earned for seed companies.

In the most difficult environments, commercialization is likely to lead to the complete abandonment of crop production, as has already occurred in parts of Asia. When there are limited opportunities for migration but environments are too marginal for specialized agricultural production to be profitable, farmers may remain on small landholdings and grow landraces for subsistence.

Even when a zone may be suitable for the production of modern varieties, the development of commercial seed systems is not sufficient to ensure that they will replace landraces in the near future because markets are imperfect. In some local communities, the specific varietal traits demanded by farmers (grain quality, fodder, and suitability for a certain soil type) cannot be obtained through the production of modern varieties or procured through impersonal market transactions so that farmers must rely on their own production or that of nearby farmers for their supply of a valued attribute. The specialized uses of certain landrace varieties for medicinal purposes, rituals and festivals, and culinary practices have been extensively documented.

Small-scale farmers' choice to grow more than one variety simultaneously is likely to reflect their need to address numerous concerns that no single variety can satisfy (Bellon, 1996). Farmers often choose to grow both landraces and modern varieties. Zimmerer (1999) found that the capacity of farmers to grow diverse food plants (including maize) in Peru and Bolivia depends on whether they can cultivate them in combination with commercially developed, high-yielding varieties. Vaughan and Chang (1992) noted that the rapid changes that occur with natural calamities are more likely to have a greater impact on the loss of rice genetic diversity than the farmer-driven, incremental changes that are regularly occurring, many of which enhance diversity (Dennis, 1987). Meng *et al.* (1998) concluded that multiple factors, including missing markets, yield risk, grain quality, and agroclimatic constraints, influence the probability that a Turkish household

will grow a wheat landrace; a change in any single economic factor is unlikely to cause farmers to cease growing it.

Viewed in the conventional microeconomic literature as partial adoption, this observed pattern has been explained theoretically through attitudes toward risk and uncertainty, nonexistent markets, and differential soil quality or nutrient response combined with fixity or rationing (Meng, 1997; Smale *et al.*, 1997). Although treated as a transitional period to full adoption (or replacement), the coexistence of modern varieties and landraces may represent an equilibrium if one or several of these aspects persist despite economic change. Then there are locally based economic incentives for farmers to continue to grow landraces.

Even when the pressures for market integration are strong, the coexistence of modern varieties and landraces may also persist with certain types of market-based incentives, as discussed previously. In the early phases of economic growth when rural populations move to urban areas, market integration exerts pressures for uniformity in the attributes of coarse grains. Localized preferences diminish in favor of cheaper, bulk-marketed grains. The elasticity of demand for staple grains declines as income increases, and it is sometimes negative. Generally, rice substitutes for maize, and wheat substitutes for rice.

The income elasticity of demand for attributes of the grains may be higher, however, than the income elasticity of demand for the cereal (Pingali *et al.*, 1997). For example, a notable pattern of rice consumption is that, with growing incomes, people express preferences for higher quality rice once their calorie needs have been met. High-income consumers spend more on rice by paying higher prices for varieties with preferred eating quality which they substitute for the lower quality variety consumed when their income levels were lower. In Asia, traditional varieties are generally of higher quality and fetch premium prices in the market. Thailand still grows low-yielding traditional rain-fed varieties extensively for the export market. When the income level was low, South Korea used to grow the modern “tongil” variety, but this was replaced by relatively low-yielding traditional *japonica* rice as consumers expressed preference for *japonicas* by offering higher prices. In response to these market signals farmers are eager to grow even low-yielding, high-quality rices because the higher prices more than compensate for their lower yields. Because rice scientists have had limited success in developing high-yielding cultivars with better eating quality, the price difference between the standard- and high-quality varieties has been increasing in Asian markets.

The post-industrial agricultural economy is characterized by growth in demand for an array of increasingly specialized goods and services. Some product quality attributes are associated with features of the production process (organic/inorganic). Some are extrinsic (origin or effects on animal welfare), whereas others cannot be discerned without laboratory tests (genetically modified organisms). The elasticity of demand for such attributes is likely to increase with very high levels of income. Under these conditions, global market integration may provide market-based incentives for continued cultivation of patches of diverse landraces. In addition to their demonstrated private economic value to the farmers who grow them, some of these hold potential for niche markets and exports.

Conclusions

In areas of the world that are more favorable for agricultural intensification, the conversion from landrace varieties to modern varieties has been almost complete for rice, wheat, and maize. In some of the remaining crop-growing environments, and especially in relatively small pockets of crop diversity called micro-centers, farmers who are linked to commercial agriculture through labor markets or specialized product markets continue to grow landraces—often in combination with modern varieties. Some cannot obtain or afford to purchase seed on a routine basis, so they both purchase and save the seed of modern types. Others purposefully adapt modern varieties to their own conditions by saving and selecting the seed, genetically integrating modern and landrace types.

The structure of genetic diversity is distinct for modern varieties and landraces. Both are essential to the future food supply. Conservationists propose that landrace diversity must be maintained not only in preserved stocks called *ex situ* collections but also *in situ*, or in the fields of farmers. The future of landrace cultivation appears to be uncertain. Although some view the replacement of landraces by modern varieties as an inevitable product of agricultural commercialization, idiosyncratic growing environments and consumer preferences may provide economic incentives for their continued cultivation by farmers—although on a limited scale. It appears unlikely that modern varieties of rice, wheat, and maize will entirely replace landraces in the near future, although it is difficult to postulate about equilibrium areas planted with each type of germplasm since the equilibrium itself shifts with technical and economic change.

Continued genetic improvement does not necessarily lead to loss of genetic diversity in areas where modern varieties dominate, especially when access to germplasm is relatively unrestricted and innovative plant breeding strategies may be employed. Access to diverse sources of germplasm is therefore of great importance to the success of public and private breeding programs for the supply of varieties in modern agriculture. The continued advances in yield potential that are a necessary (although not a sufficient) condition for alleviating hunger are thought to depend on increasingly complex combinations of genes and novel alleles. Landraces and wild relatives have served as repositories for resistance to biotic and abiotic stress when these are absent in advanced breeding materials. Even in the parts of the world where the “ancient patterns of diversity” may still be found, access to the products of modern plant breeding is often integrated economically or genetically to generate more resilient and sustainable systems.

Agriculture, Nutrient Management, and Water Quality

Andrew N Sharpley, University of Arkansas, Fayetteville, AR, USA

Published by Elsevier Inc.

Glossary

Beneficial management practices (BMPs) BMPs are effective, practical, structural, or nonstructural methods that are designed to prevent or reduce the movement of sediment, nutrients, pesticides, and other chemical contaminants from the land to surface or ground water, or that otherwise protect water quality from the potential adverse effects of agricultural activities. These practices are developed to achieve a cost-effective balance between water quality protection and the agricultural production (e.g., crop, forage, animal, and forest).

Concentrated animal feeding operations (CAFOs) A CAFO is an animal feeding facility that confines animals for more than 45 day in an area that does not produce vegetation during the growing season.

Conservation practices Any action taken to produce environmental improvements, particularly with respect to agricultural nonpoint-source emissions. The term is used broadly to refer to structural practices, such as buffers, as well as nonstructural practices, such as in-field nutrient management planning and application. Conservation Practice standards have been developed by NRCS and are available at: <http://www.nrcs.usda.gov/Technical/Standards/nhcp.html>

Edge-of-field nutrient loss A term that refers to the nitrogen and phosphorus that is lost or exported from fields in agricultural production.

Eutrophication An increase in the rate of supply of organic matter to an ecosystem.

Nonpoint source A diffuse source of chemical and/or nutrient inputs not attributable to any single discharge (e.g.,

agricultural runoff, urban runoff, and atmospheric deposition).

Nutrients Inorganic chemicals (particularly nitrogen, phosphorus, and silicon) required for the growth of animals and plants, including crops and phytoplankton.

Point sources Readily identifiable inputs where treated wastes are discharged from municipal, industrial, and agricultural facilities to the receiving waters through a pipe or a drain.

Water quality standards Risk-based requirements, which set site-specific allowable pollutant levels for individual water bodies, such as rivers, lakes, streams, and wetlands. States set water quality standards by designating uses for the water body (e.g., recreation, water supply, aquatic life, and agriculture) and applying water quality criteria (numeric pollutant concentrations and narrative requirements) to protect the designated uses.

Water-use designation The water quality standards regulation requires that States and authorized Indian Tribes specify appropriate water uses to be achieved and protected. Appropriate uses are identified by taking into consideration the use and value of the water body for public water supply, for protection of fish, shellfish, and wildlife, and for recreational, agricultural, industrial, and navigational purposes. In designating uses for a water body, States and Tribes examine the suitability of a water body for the uses based on the physical, chemical, and biological characteristics of the water body, its geographical setting and scenic qualities, and economic considerations.

Watershed The drainage basin contributing water, organic matter, dissolved nutrients, and sediments to a stream or a lake.

Introduction

Since the late 1960s, point sources of water pollution have been reduced in the US due to their ease of identification and the passage of the Clean Water Act in 1972. However, water quality problems remain, and as further point-source control becomes less cost-effective, attention is being directed toward the role of agricultural nonpoint sources in water quality degradation. In a 1996 U.S. Environmental Protection Agency (EPA) report, nonpoint-source nutrients were the primary source of concern in 40% of rivers, 50% of lakes, and 60% of estuaries surveyed and listed as impaired (U.S. Environmental Protection Agency, 1996). As in the US, the European Union Water Framework Directive (WFD) (Council of European Communities, 2000) now requires widespread control of N and P inputs to rivers specifically to improve riverine ecology (Hilton *et al.*, 2006).

Besides soil and pesticide loss from agriculture, most environmental concerns center on nonpoint transport of the

nutrients phosphorus (P) and nitrogen (N), which are essential inputs for optimum crop and animal production. However, dramatic improvements in the economic efficiency of grain and animal production over the past 50 years have been coupled with increasing surface and ground water quality problems (Boesch *et al.*, 2001; Rabalais *et al.*, 2001). Owing to its much lower mobility in soil, P concerns focus mainly on its transport in surface runoff, whereas N concerns revolve around nitrate movement through the soil profile to ground water (Figure 1).

Phosphorus inputs to fresh waters can accelerate eutrophication (Carpenter *et al.*, 1998; Schindler, 1977). Although nitrogen and carbon (C) are also essential to the growth of aquatic biota, most attention has focused on P because of the difficulty in controlling the exchange of N and C between the atmosphere and water, and fixation of atmospheric N by some blue-green algae. Thus, control of P inputs is critical to reducing freshwater eutrophication. For water bodies with a naturally higher salt content, as in estuaries, there

Figure 1 Factors affecting the fate of N and P in agriculture, representing their potential impact on soil, water, and air quality. Numbers in parentheses are based on an approximate farm nutrient balance and the relative fate of N and P as a percentage of load (Farm inputs) or percentage of fertilizer and manure (Nutrient use and land management). American Society of Agronomy Monograph. Madison, WI: American Society of Agronomy.

are likely unique site-specific critical concentrations of both N and P that generally limit aquatic productivity (Howarth *et al.*, 2000).

Eutrophication has been identified as the main problem in surface waters with impaired water quality (U.S. Environmental Protection Agency, 2002). Eutrophication restricts water use for fisheries, recreation, industry, and drinking, due to the increased growth of undesirable algae and aquatic weeds and oxygen shortages caused by their death and decomposition. Also, many drinking water supplies throughout the world experience periodic massive surface blooms of cyanobacteria (Kotak *et al.*, 1993). These blooms contribute to a wide range of water-related problems including summer fish kills, unpalatability of drinking water, and formation of trihalomethane during water chlorination (Kotak *et al.*, 1994; Palmstrom *et al.*, 1988). Consumption of cyanobacterial blooms or water-soluble neuro- and hepatotoxins released when these blooms die can kill livestock and may pose a serious health hazard to humans (Lawton and Codd, 1991; Martin and Cooke, 1994). Recent outbreaks of the dinoflagellate *Pfiesteria piscicida* in the eastern US coastal waters have been linked to excess nutrients in affected waters (Burkholder and Glasgow, 1997). Neurological damage in people exposed to the highly toxic volatile chemical produced by this dinoflagellate has dramatically increased public awareness of eutrophication and the need for solutions.

Nitrate is a water quality concern because it has been linked to methemoglobinemia in infants, to toxicities in animals, and to increased eutrophication in both fresh and saline (e.g., estuaries) waters (Amdur *et al.*, 1991; Sandstedt, 1990). The EPA has established a maximum contaminant level for nitrate-N in drinking water of 10 mg l⁻¹ (45 mg nitrate per

liter) to protect babies under 3–6 months of age (U.S. Environmental Protection Agency, 2002). This segment of the population is most sensitive because bacteria that live in an infant's digestive tract can reduce nitrate to nitrite, thereby causing hemoglobin to transform into methemoglobin, which interferes with the oxygen-carrying ability of blood (Amdur *et al.*, 1991). Under anaerobic soil conditions, denitrifying bacteria readily convert excess nitrate into N gases (primarily N₂), reducing the quantity of nitrate that can potentially leach to ground water supplies. However, the production of N_xO gases contributes to the accumulation of greenhouse gases in the atmosphere (Figure 1).

To address these problems with drinking water treatment, some areas, such as New York State, now treat the cause of eutrophication rather than its effects. In the early 1990s, New York City decided that remediation of the sources nutrients in its water supply watersheds was more economical than building a new \$8-billion water treatment facility. For agricultural land, progress has been made in developing and implementing farm-specific management plans and best management practices. Other nutrient management programs mandated include storm water management, septic system rehabilitation and replacement, and forestry management programs.

Research has identified agricultural land-use practices that are of highest risk for nutrient loss at field and farm scales, and the forms in which N and P are exported (Sharpley *et al.*, 2005; Withers and Lord, 2002). Their impact on stream water quality at a watershed scale is less well defined because field and farm inputs are modified by watershed hydrology, in-stream processing, and contributions from a diverse range of other rural nutrient sources, including farmyard and septic tanks runoff

and rural sewage treatment works (Jarvie *et al.*, 2006 Gburek and Sharpley, 1998). In response, new requirements to improve the ecological status of rivers focus attention on identifying nutrient sources and their ecological impacts in rivers.

Phosphorus and N are typically treated separately by scientists and environmental managers, but such a separation is artificial as P and N occur simultaneously in watersheds and farmers manage them together.

Water Quality Criteria

Guidelines for management within agricultural catchments are based on definitions of impairment and acceptable conditions. U.S. EPA established the National Regional Nutrient Criteria Program (Table 1; U.S. Environmental Protection Agency, 2001). Similarly, in Europe, the EU WFD requires the setting of “reference conditions” for different water body types to define how far they have become impaired (Council of European Communities, 2000). Reference condition is defined as “no or only very minor alterations” resulting from human activities to the water body’s physiochemical, biological, and hydrological properties.

In the US, baseline or reference conditions of pristine waters are defined by monitoring total P, total N, chlorophyll-*a*, and clarity in waters draining areas with minimal human impact (Gibson *et al.*, 2000). Because it can be argued that most, if not all, lakes have been impacted by human activity to some degree, reference conditions represent the least impacted conditions or what is considered to be most attainable. The following guidelines are used to define minimally impacted lakes: catchments with <1% urban land use, >65% of lakeshore that has at least 10 m of natural bank-side vegetation, no point source discharge inputs, and there is no control of water-level

fluctuations (Gibson *et al.*, 2000). Baseline concentrations of total N and P for freshwater systems in the continental US are shown in Table 1. The difference between baseline and current N and P levels is used to determine and target reductions required in a catchment to alleviate water quality impairment. In the EU, countries have governmental powers to implement the WFD and water quality goals are achieved through river basin management planning.

Even so, water quality concerns associated with agriculture have arisen at a catchment rather than farm scale, reflecting the cumulative impacts of individual nutrient and land management activities on farms. In many areas, agriculture’s contribution to water quality impairment has been, or is, masked by nonagricultural nonpoint and point sources to varying degrees. This raises issues of scale (both spatial and temporal), difficulties attributing cause and effect to ensure adaptive management, and the need to consider interactions with other nutrient sources, which must all be taken into account when developing catchment strategies for agricultural management that sustain productive viability and maintain water quality.

The Evolution of Agriculture

After World War II, fertilizer production and distribution became cheaper. Between 1950 and 1990, N use in the US increased fourfold (8.5 million tons) and P use two fold (0.9 million tons) and agricultural production more than doubled (Evans *et al.*, 1996). US farm land decreased from 500 to 400 million ha (20%) and the number of farms from 5.6 to 2.1 million (63%), whereas the average farm size has increased from 90 to 200 ha (120%). There was also a switch from crop- to livestock-based systems in states such as Alabama, Arkansas, Delaware, North Carolina, and Texas (Kellogg *et al.*, 2000;

Table 1 Baseline N and P concentrations for each of the aggregated nutrient Ecoregions in the US for freshwater systems

Aggregated ecoregion		Total N (mg l ⁻¹)		Total P (μg l ⁻¹)

Source: Adapted from U.S. Environmental Protection Agency (2001) *Ecoregional Nutrient Criteria*. EPA-822-F-01-010. USEPA, Office of Water (4304). Washington, DC: U.S. Government Printing Office, <http://www.epa.gov/waterscience/criteria/nutrient/9docs.pdf>.

Figure 2 Grain and animal production systems have evolved in spatially separate areas leading to localized accumulations of nutrients in manure.

Lanyon, 2000). Over the past 10 years, the number of dairies has decreased by 40%, but herd size has increased by 50%, whereas the number of hogs has increased 18% on 72% fewer farms. Similarly, 97% of poultry production comes from farms with more than 100,000 birds and over a third of beef production from <2% of the feedlots. As a result of this regional intensification, modern farming systems have become fragmented, with increasing separation of crop and livestock production, even across regional boundaries (Lanyon, 2005). Similar trends occurred in Europe (Withers *et al.*, 2002).

As a consequence of the spatial separation of crop and animal production systems, fertilizers are produced (i.e., N) or imported (i.e., P) to areas of grain production (Figure 2). The grain and harvested N and P are then transported to areas of animal production, when inefficient animal utilization of nutrients in feed (<30% utilized) is excreted as manure. This has led to a large-scale, one-way transfer of nutrients from grain- to animal-producing areas and dramatically broadened the emphasis of nutrient management strategies from field and watershed levels to national scales (Figure 2; Lander *et al.*, 1998; Lanyon, 2005; Sharpley *et al.*, 2005). In the western US, irrigated lands, animal production, and grain production areas are still contiguous; however, large-scale consolidation has created much larger concentrated animal feeding operations (CAFOs), which makes economical redistribution of manure to croplands difficult (Kellogg *et al.*, 2000).

Managing Nutrients in Agriculture

The Fate of N and P in Agriculture

The fate of N and P in agriculture is depicted in Figure 1. Approximate percentage inputs of N and P, as feed or fertilizer, and their respective fate when fed to animals or applied to land, were obtained from several studies, as summarized below.

Nitrogen

About 30% of feed N is accounted for in animal products sold, with the remainder excreted in manure and available for land application. In rain-fed systems, an average of 40–60% of the N applied in fertilizer and manure is removed in crop harvest (Figure 1; Howarth *et al.*, 2000). Of the remainder, some is stored as organic N in the soil, some is volatilized to the atmosphere, and some leaches to ground and surface waters. A variety of factors, including soil properties, climate, fertilizer, manure, and land management, influence the fate of applied N (Howarth *et al.*, 1996). For typical rain-fed farming in the US, roughly 15% of field-applied N is volatilized to the atmosphere as ammonia and N_2O (Figure 1; Bouwman and Booi, 1998). This N is deposited back onto the landscape, often near the source of volatilization, although sometimes traveling long distances within an airshed (Holland *et al.*, 1999). Again, for typical farming systems in the US, the percentage of applied N that leaches to ground and surface waters varies between 10% and 40% for loam and clay soils, and 25% and 80% for sandy soils (Howarth *et al.*, 1996).

As a consequence of irrigation in the western US, the nitrate concentration has increased in shallow aquifers underlying major grain and livestock production areas (CAST, 1985; Powers and Schepers, 1989). Corn is the primary crop that receives most of the N fertilizer and manure. Most of the leaching losses occur during the nongrowing season because rainfall and irrigation during the peak growing season often just meet crop water requirements. If excess irrigation results in too high a soil moisture content at the end of the season, any nitrate remaining in the soil may be leached during the following spring and fall when rainfall often exceeds evapotranspiration demands (Hergert, 1986; Klocke *et al.*, 1999).

Phosphorus

Less than a third of feed P is utilized by animals, with the remainder excreted in manure and applied to land for crop use. Several soil and crop factors, including soil P sorption

capacity, crop type, P application type, method and rate, and land management, influence plant P uptake (Pierzynski and Logan, 1993; Sims and Sharpley, 2005). Phosphorus loss by leaching is generally greater in sandy, organic, or peaty soils – those with low-P adsorption capacities, and in soils with substantial preferential flow pathways (Bengtson *et al.*, 1988; Sharpley and Syers, 1979; Sims *et al.*, 1998) (Figure 1). Phosphorus losses from tile-drained fine-textured soils receiving manure are generally low (Hergert *et al.*, 1981). Soils that allow substantial subsurface export of dissolved P are common in parts of the northeast Coastal Plains region of the Delmarva Peninsula, and are important to consider in minimizing coastal water eutrophication in these regions. However, P loss in surface runoff is generally greater than in subsurface flow, depending on the rate, time, and method of P application; form of fertilizer or manure applied; amount and time of rainfall after application; and land cover (Sharpley and Rekolainen, 1997).

Phosphorus losses are often agronomically small (generally <2 kg P per hectare), representing a minor proportion of applied fertilizer or manure P (generally <5%). Phosphorus uptake and harvest removal by crops ranges from 10% to 40% of applied P (Figure 1), due to the rapid and only slowly reversible sorption of P to Al, Fe, and Ca compounds in soil.

Farm Inputs and Nutrient Balances

The potential for P and N surplus at the farm scale can be much greater in CAFO than in cropping systems when nutrient inputs become dominated by feed rather than fertilizer (Table 2). A CAFO is defined as an animal feeding facility that confines animals for more than 45 days in an area that does not produce vegetation during the growing season (see <http://www.epa.gov/region07/water/cafo/>). With a greater reliance

on imported feeds, only 30% of P and 55% of N in purchased feed for a 74,000 layer operation on a 12-ha farm in Pennsylvania could be accounted for in farm outputs (Table 2). These nutrient budgets clearly show that the largest input of nutrients to CAFOs, and thus the primary source of any on-farm nutrient excess, is in animal feed. Similar annual surpluses of N and P were reported for grain-poultry farms in Delaware (Sims, 1997) and grain-dairy farms in Wisconsin (Bundy and Kelling, 2001; Powell *et al.*, 2002) and New York (Klausner *et al.*, 1998). Results of US census surveys over the past 15 years show a steady increase in the amount of N and P that exceeds crop requirements at a farm level for all livestock operations (Kellogg *et al.*, 2000). Thus, many of the water quality concerns we now face are a result of this imbalance in system inputs and outputs of P and N, caused by the intensification of CAFOs.

Regional Nutrient Imbalances

The already difficult nutrient management implications of this spatial separation and intensification of grain and animal production in farming systems are exacerbated by the localization of the problem to specific areas (Figure 2). The increasing livestock density in certain regions of the US is due, in part, to strategic planning by the animal industry and market integrators, economic pressures, and consumer demands, all of which are external to individual farmer decisions. This has led to an accumulation of manure N and P in certain regions. Kellogg *et al.* (2000) estimated the amount of manure produced from animal distribution numbers from the 1997 US Census of Agriculture (Figure 3), using standard values of manure production and nutrient concentration for each animal type. Estimates of excess N and P were calculated based on crop N and P removal (Lander *et al.*, 1998) and the

Table 2 Farming system and nutrient budget

Farming system	Nutrient input in		Output in produce (kg ha ⁻¹ year ⁻¹)	Surplus (kg ha ⁻¹ year ⁻¹)
	Feed (kg ha ⁻¹ year ⁻¹)	Fertilizer (kg ha ⁻¹ year ⁻¹)		
Nitrogen budget				
Cash crop ^a	–	246	238	8
Dairy ^b	155	40	75	120
Hog ^c	390	10	120	280
Poultry ^d	5800	–	1990	3810
Phosphorus budget				
Cash crop ^a	–	59	38	21
Dairy ^b	30	11	15	26
Hog ^c	105	–	30	75
Poultry ^d	1560	–	440	1120

^a30 ha cash crop farm growing corn, alfalfa, and hay; "output in produce" includes nitrogen fixed by alfalfa (79 kg nitrogen per hectare per year) not otherwise tallied in the nutrient inputs.

^b40 ha farm with 65 dairy Holsteins averaging 6600 kg milk per cow per year, 5 dry cows, and 35 heifers. Crops were corn for silage and grain, alfalfa, and rye for forage.

^c30 ha farm with 1280 hogs; surplus includes 36 kg phosphorus and 140 kg nitrogen per hectare per year manure exported from the farm.

^d12 ha farm with 74,000 poultry layers; surplus includes 180 kg phosphorus and 720 kg nitrogen per hectare per year manure exported from the farm.

In: Sharpley AN (ed.) *Agriculture and Phosphorus Management: The Chesapeake Bay*, pp. 145–158. Boca Raton, FL: CRC Press, and Bacon SC, Lanyon LE, and Schlauder Jr. RM (1990) Plant nutrient flow in the managed pathways of an intensive dairy farm. *Agronomy Journal* 82: 755–761.

Figure 3 (a) Excess manure N assuming no export of manure from the farm using 1997 census data. (b) Excess manure P assuming no export of manure from the farm, using 1997 census data.

assumption that all suitable crop and pasture land was available for manure application (Figure 3; Kellogg *et al.*, 2000). Most areas with CAFOs have some excess N (Figure 3(a)) and P (Figure 3(b)). The regions of greatest excess are generally in

animal production areas of the southern tier states. With the exception of the Midwest and central Great Plains, where P excesses were substantially greater than N, most regions had similar amounts of excess N and P in manure (Figure 3).

The significance of these regional N and P accumulations is highlighted by their close proximity to nutrient-sensitive waters in these regions (e.g., Neuse River, North Carolina; Chesapeake Bay; Great Lakes; Lake Champlain; Gulf of Mexico; Illinois River water supply, Arkansas and Oklahoma; and North Bosque River, Texas). Kellogg (2001) combined an assessment of the excess amounts of N and P in manure relative to potential crop assimilation (Figure 4), with environmental factors governing their potential for loss to surface and ground water; these factors included rainfall and the leaching, runoff, and erosion potential of area soils. The resulting nitrate leaching and P vulnerability indices are presented in Figure 4(a) and 4(b), respectively. This approach allowed Kellogg (2001) to identify potential priority watersheds for water quality protection, where both high manure nutrients can be applied to the land and environmental indicator scores are higher than other areas of the country. These would be the watersheds where government programs could be targeted first to quickly meet the goals of protecting watersheds from contamination by manure nutrients. The “environmental setting” is not addressed by these vulnerability indexes. For example, some areas of the country, such as the Chesapeake Bay and Florida, have a greater potential for use impairment than other areas of the country because of the high demand for use of the water resource for recreation, commercial activities, shoreline housing, drinking water, and general esthetics. Even so, while these maps were developed a decade ago, priority areas are still the same and the same challenges remain.

In the Great Plains, desirable topography and climate are the primary reasons contributing to a major increase in cattle feeding during the past 20 years (Kellogg *et al.*, 2000). A large portion of the grain production in this region occurs on irrigated lands that rely on ground water sources. Much of the intermountain west and the far west rely on surface water from reservoirs, but there is also substantial irrigation from ground water (Spalding and Exner, 1993). A major impact from concentrated livestock operations in these regions is nitrate enrichment of ground water. Because these regions have typically low rainfall amounts, surface runoff is limited, and denitrification, which decreases the impact of nitrate available for enrichment of ground water, is less of a factor than it is in the humid east. Instances of high nitrate in ground water, of which a part of the source can be traced to manure, include Nebraska, Minnesota, Kansas, Colorado, Arizona, New Mexico, Texas, and California.

Remedial Beneficial Management Practices (BMPs)

There are many BMPs that can be implemented over a wide range of scales to minimize the loss of N and P from agriculture to surface and ground waters (Table 3). These are commonly grouped into measures that seek to reduce the input of N and P onto farms and ring them into closer balance with outputs in produce; manage on-farm nutrient sources through appropriate rate, timing, and method of N and P application; and measure the potential for N and P transport to surface and ground waters (Table 3). These measures are also depicted in Figure 5.

Farm Input Decisions

Approximately 70% of the N and P fed to animals is excreted (Figure 1; Lanyon, 2005); thus, managing animal nutritional requirements is critical to on-farm N and P management. However, several surveys conducted in the Northeast (Tylutki and Fox, 2000), Midsouth States (Sansinena *et al.*, 1999), and Wisconsin (Powell *et al.*, 2001) indicate that P was fed 30–40% above the National Research Council (2001) dietary guidelines of about 0.36% P. There are several reasons for this overfeeding of P, which include rations formulated with wide “safety margins” or “insurance” levels of P, a lack of ration formulation based on animal groups, and relatively inexpensive P supplements (CAST, 2002; Dou *et al.*, 2001).

Carefully matching dietary P inputs to animal requirements can reduce the amount of P excreted by animals (Poulsen, 2000; Valk *et al.*, 2000). For instance, in a survey of Wisconsin dairy farms, Powell *et al.* (2001) found that decreasing dietary P level from an excessive 0.55% P to the National Research Council (NRC) level of 0.36% P would reduce the number of farms and acreage with an excess P balance by approximately two-thirds (Powell *et al.*, 2002). Recently, Ebeling *et al.* (2002) showed that increasing the P concentration in a dairy cow diet increased the potential for P loss in runoff from land-applied manures, even with similar P application rates. This difference is likely due to a greater proportion of manure P being water soluble in high-P (40%) than low-P diet manure (29%). Similar trends of increased P loss in runoff as a function of greater water-soluble manure P are also evident for bee, pigs, and poultry (Kleinman *et al.*, 2002, 2005b).

Implementing a carefully planned diet tailored to meet the specific N and P requirements of animals in each phase of their growth will minimize nutrient loss to the environment in feces, urine, and gases. Reducing farm inputs of N and P in animal feed is a very effective BMP that can contribute to bringing about a lasting decrease in N and P loss to the environment. This is a direct result of the fact that farm N and P surpluses are governed by feed imports (Table 2), as well as the fact that farm-gate inputs of fertilizer N and P can be carefully matched to crop needs by plant tissue and soil testing. Other nutrient management measures (Table 3) are generally aimed at decreasing the potential for N and P loss and seen as short-term “band aids” and not solutions to environmental concerns.

Increase Nutrient-Use Efficiency in Animals

A reduction in the quantity of N and P excreted by livestock can be accomplished by supplementing livestock diets with enzymes to enhance the digestion of feedstuffs. Research indicates that an enzyme-treated diet decreased total N excretion 6% in late-lactating cows but increased N excretion by 3% in early-lactating cows (Knowlton *et al.*, 2002). A concurrent decrease (9.3 g day⁻¹ or 10.1%) in total P excretion was observed in the early-lactating cows, but a change was not observed in the late-lactating cows. The results of adding amino acids and phytase to the diet of laying hens were much more dramatic. Daily total N and P excretion was reduced 45% and 48%, respectively (Keshavarz and Austic, 2003). Although a marked decrease in total N and P excretion was observed in

Figure 4 (a) Leaching vulnerability index for manure N available for land application, using 1997 census data. (b) Runoff vulnerability index for manure P available for land application, using 1997 census data.

Table 3 Beneficial management practices to minimize the loss of N and P from agriculture

Practice	Description	Impact on loss ^a	
		N	P
<i>Farm inputs</i>			
Crop hybrids	Low phytic acid corn reduces P in manure	Neutral	Decrease
Feed additives	Enzymes increase nutrient utilization by animals	Decrease	Decrease
Feed supplements	Match animals nutritional requirements	Decrease	Decrease
<i>Source management</i>			
Crop requirements	Nutrient applications based on crop N and/or P needs	Decrease	Decrease
Presidedress N Test	Can aid accurate split N applications	Decrease	Neutral
Soil P testing	Nutrient applications based on soil P availability	Neutral	Decrease
Tissue testing	N applications can be tailored to crop needs	Decrease	Neutral
Cover crops/residues	If harvested can reduce residual soil nutrients	Decrease	Decrease TP increase DP
Site-specific management	Use of Geographical Information System (GIS) and Global Positioning Systems (GPS) to apply and manage nutrient sources	Decrease	Decrease
Method of application	Incorporated, banded, or injected in soil	Decrease	Decrease
Rate of application	Match crop needs	Decrease	Decrease
Source application	Sources can differ in their P and N availability	Decrease	Decrease
Timing of application	Avoid application to frozen ground Apply during season with low runoff probability	Decrease	Decrease
<i>Transport management</i>			
Conservation tillage	Reduced and no-till increases infiltration and reduces soil erosion	Decrease TN increase NO ₃	Decrease TP increase DP
Strip cropping, contour tillage, and terraces	Reduces transport of sediment-bound nutrients	Decrease TN neutral NO ₃	Decrease TP neutral DP
Conservation cover	Permanent vegetative cover increases soil infiltration and water holding capacity	Decrease	Decrease
Invert stratified soils	Redistribution of surface P through profile by plowing	Neutral	Decrease
Buffer, riparian, wetland areas, and grassed waterways	Removes sediment-bound nutrients, enhances denitrification	Decrease	Decrease TP neutral DP
Critical source area treatment	Target sources of nutrients in a watershed for remediation	Decrease	Decrease

^aTN is total N, NO₃ is nitrate, TP is total P, and DP is dissolved P.

**Figure 5** The management of N and P in agricultural systems.

this poultry study, the cost of the successful amino acid-supplemented diet was \$311 compared with \$126 t⁻¹ for the control diet. Despite these dramatic results, the economic incentive to implement these new diets may not exist.

Corn hybrids are also available that contain low amounts of indigestible phytate P. Pigs and chickens fed "low-phytic acid" corn grain excreted less P in manure than those fed conventional corn varieties (Ertl *et al.*, 1998). This study also showed that P availability to nonruminants from low-phytate, high-available phosphate corn is about two to three times higher than from normal corn. Currently, the challenge to plant breeders is to incorporate the low-phytate trait into commercial grain hybrids with other agronomically desirable traits.

Nutrient Management

Soil and Plant Testing

Considerable attention has been paid to developing soil N tests for corn, with the preplant nitrate test successfully used in semiarid regions of the Western and Great Plains (Hergert, 1987); however, the preplant nitrate test does not work well in more humid regions (Bundy *et al.*, 1999). The preplant tests' lower success rate in more humid climates results from the increased probability of leaching and denitrification that occurs between soil sampling and plant N demand, as well as not representing the amount of N mineralization that might occur during the growing season. A modified approach to the preplant was proposed by Magdoff *et al.* (1984) to be used in the more humid corn production areas, known as the pre-sidedress soil nitrate test to determine if and how much N fertilizer is needed to supplement any early season N mineralization. These soil nitrate tests are effective methods for reducing the amount of N fertilizer applied to corn, which reduces nitrate leaching potential by avoiding N applications in excess of plant requirements, although the window of opportunity between soil sampling and N fertilizer application is very small – an obstacle for many producers.

Because N availability is a function of multiple processes within the soil, varying spatially and temporally, more recent research efforts have focused on methods that evaluate the N status of the growing crop. Varvel *et al.* (1997) demonstrated that chlorophyll meters could be used as an index for N status in corn, and N fertilizer-use efficiency could be improved with this technique. Remotely sensing crop reflectance has been successfully used in a similar capacity, detecting N deficiency (Osborn *et al.*, 2002) and using an index for developing N recommendations.

Fertilizer P rates are usually established by crop need and modified by the amount already in the soil, as determined by established soil test P methods (Cox, 1994). In the case of commercial fertilizer P, applications can easily be tailored to match crop needs and minimize excessive soil P accumulation, because an economic disincentive exists to avoid applying excess fertilizer P. For instance, Dodd and Mallarino (2005) showed that annual fertilizer P rates of about 15 kg P per year maintained near-optimum soil test P levels (16–20 mg kg⁻¹ as Bray-1P) and corn-soybean (*Glycine max* (L.) Merr.) yields for Mollisols in Iowa. However, applications

of manure have, until recently, been made to meet the N needs of the crop, which has resulted in the build-up in soil test P above levels needed for optimum crop yields, and increases the risk of P loss in runoff (Daverede *et al.*, 2003; Pote *et al.*, 1996; Torbert *et al.*, 2002).

Application Method

Nitrogen fertilizers are applied by various methods, including injection, broadcasting, banding, and with irrigation water. The method selected usually depends on the machinery, fertilizer type, and compatibility with a farmer's overall crop management practices and usually has little impact on crop response to or environmental impact of the fertilizer. There are three exceptions: (1) when urea is applied to the soil surface, especially in no-till, (2) when N fertilizer is band-applied or injected into a microfeature that improves localized water infiltration, and (3) when N fertilizer is sprinkler-applied on sandy soils.

Urea applied to the soil surface is susceptible to considerable loss as volatilization of ammonia gas (as much as 30% of applied N; Fox *et al.*, 1986). Urea volatilized as ammonia poses an environmental risk as atmospheric ammonium fall-out. Ammonium deposition poses an environmental threat to pristine ecosystems that are sensitive to slight changes in N inputs (e.g., estuaries or native forests); however, the impact of ammonia volatilization from urea fertilizers on such ecosystems is not fully understood.

Because of the relative immobility of P in the soil profile, placement of fertilizer P generally is more critical for plant availability than in the case of fertilizer N. Long-term studies in the northern Great Plains show that high rates of broadcast P (90 kg P per hectare) can have long-term effects (17 years) on soil test P, wheat yields (Halvorson and Black, 1985) and profitability (Jose, 1981; Halvorson *et al.*, 1986). Several studies show a greater yield response to surface or subsurface band application of fertilizer P at low rates, compared with broadcasting or mixing (Bailey and Grant, 1989; Lamond, 1987). In fact, Welch *et al.* (1966) observed greater P uptake and yield for corn with a combined banded (50%) and broadcast (50%) application (40 kg ha⁻¹).

Manure application methods and timing relative to rainfall influence the concentration of N and P in runoff (Dampney *et al.*, 2000; Sims and Kleinman, 2005). Several studies show, for example, reductions in N and P losses with an increase in the length of time between manure application and surface runoff (Djodjic *et al.*, 2000; Edwards and Daniel, 1993; Sharpley, 1997). These reductions can be attributed to the reaction of added P with soil and dilution of applied P by infiltrating water from rainfall that did not cause surface runoff. The incorporation of manure into the soil profile, either by tillage or by subsurface placement, reduces the potential for P loss in surface runoff. Rapid incorporation of manure also reduces ammonia volatilization and potential loss in runoff, as well as improving the N : P ratio for crop growth. For example, Mueller *et al.* (1984) showed that incorporation of dairy manure by chisel plowing reduced total P loss in runoff from corn 20-fold, compared with no-till areas receiving surface applications. In fact, P loss in runoff declined because of a lower concentration of P at the soil surface and a reduction in runoff with incorporation of manure (Mueller *et al.*, 1984; Pote *et al.*, 1996).

Rate and Frequency of Application

Nitrogen fertilizer should be applied nearest the time when needed by a crop. This minimizes opportunities for leaching below the root zone or gaseous losses via denitrification and, consequently, should result in the greatest proportion of applied N used by the crop. Although farmers might recognize this situation, deciding when to apply fertilizer depends on logistical and time constraints unique to every farm. Often, N fertilizer is applied much earlier than required by the crop. In the upper Midwest and Northeast, farmers sometimes are faced with the opportunity to apply N fertilizer on frozen soils. As a general rule, fertilizer should be applied when runoff potential is low. Fertilizer application to frozen soils should be avoided.

Many studies show that the loss of P in runoff relates directly to the rate and frequency of applied fertilizer P (Sharpley *et al.*, 2007; Sims and Kleinman, 2005). Avoiding fertilizer applications within a few days of expected rainfall can minimize runoff losses (Sims and Kleinman, 2005). Even so, fertilizer rates can easily be tailored to crop needs on the basis of soil test P, minimizing the potential for soil P build up and P loss in runoff. In fact, the use of fertilizer P has declined steadily since 1995 (Howarth *et al.*, 2000). This decline is most likely due to greater awareness and advice on the large savings in fertilizer costs afforded by nutrient management planning on farms.

Rainfall intensity and duration, as well as when rainfall occurs relative to when manure is applied, are all factors that influence the concentration and overall loss of manure N and P in runoff. The relationship between potential loss and application rate, however, is critical to establishing BMP strategies. Although soil P clearly is important in determining P loss in surface runoff, the rate and frequency of applying P to soil can override soil P in determining P loss (Sharpley *et al.*, 2007). Also evident are the long-lasting effects of applied manure on increased concentrations of P in surface runoff. For instance, Pierson *et al.* (2001) found that a poultry litter application tailored to meet pasture N demands elevated surface runoff P for up to 19 months after application. Although few studies have evaluated the loss of P in surface runoff as a function of application frequency, more frequent manure applications can be expected to increase soil P rapidly (Haygarth *et al.*, 1998; Sharpley *et al.*, 1993; 2004; Sims *et al.*, 1998), with a concomitant increase in runoff P loss.

Transport Management

Runoff Potential

The potential for runoff from a given site is important in determining the loss of P and, to a lesser extent, N and is thus a

critical component of nutrient management strategies. For instance, Pionke *et al.* (1999 and 2000) generalized that about 90% of annual P export ($0.63 \text{ kg ha}^{-1} \text{ year}^{-1}$) from an agricultural watershed in the Chesapeake Bay Basin occurs during storm flow as a result of runoff from saturated areas extending no more than 60 m from the stream channel. In contrast, only 20% of N ($6 \text{ kg ha}^{-1} \text{ year}^{-1}$) is exported annually in storm runoff. Distance from where runoff is generated to a stream channel influences N and P loss and thus must be a nutrient management consideration (Gburek and Sharpley, 1998). Runoff, and nutrients carried by it, can be reduced or even intercepted by infiltration and deposition, respectively, before reaching a stream channel. Generally, the further a field is from a stream channel, the lower the potential for runoff to contribute nutrients to the stream. Many states, therefore, have adopted the premise of implementing more restrictive nutrient management strategies, particularly for P, on fields close to streams (Sharpley *et al.*, 2003).

Erosion Potential

A sequence of changing tillage practices in several watersheds in Oklahoma enabled comparison of surface and ground water impacts associated with native grass, conventionally tilled wheat, and no-till wheat (Sharpley and Smith, 1994). In the late 1970s, conversion of native grass to conventionally tilled wheat increased soil loss dramatically (Table 4). From 1979 to 1990, fertilizer N and P applications associated with conventionally tilled wheat also contributed to increased losses (3.74 kg N and 0.55 kg P per hectare per year) in surface runoff compared with native grass (Table 4). Over the same period, dissolved P and total P concentrations in surface runoff averaged 0.20 and 4.50 mg l^{-1} , respectively, whereas nitrate-N in ground water under two conventionally tilled wheat watersheds averaged 4.5 mg l^{-1} (Figure 6). Following conversion of two watersheds to no-till wheat in 1984, the total P concentration in runoff declined 25-fold by 1995, to 0.18 mg l^{-1} (Figure 6). This related to $18.9 \text{ kg ha}^{-1} \text{ year}^{-1}$ less total N and $3.44 \text{ kg ha}^{-1} \text{ year}^{-1}$ less total P in surface runoff from no-till wheat than conventionally tilled wheat (Table 4). However, both the dissolved P concentration (0.20 – 0.75 mg l^{-1}) and loss in runoff (0.26 – $0.74 \text{ kg ha}^{-1} \text{ year}^{-1}$), as well as nitrate-N in ground water, increased (4.5 – 29.0 mg l^{-1}) following the conversion to no-till wheat (Figure 6 and Table 4).

Similar amounts of fertilizer P and N were applied to the conventionally tilled and no-till wheat watersheds (about 12 kg N and 60 kg P per hectare per year; Sharpley and Smith, 1994). The increase in nitrate leaching, therefore, might be

Table 4 Annual sediment, N, and P loss as a function of tillage management of watersheds at El Reno and Woodward, Oklahoma

Study period	Management	Sediment ($\text{kg ha}^{-1} \text{ year}^{-1}$)	Dissolved P ($\text{kg ha}^{-1} \text{ year}^{-1}$)	Total P ($\text{kg ha}^{-1} \text{ year}^{-1}$)	Total N
1977–1978	Native grass	103	0.03	0.08	0.50
1979–1983	Native grass	38	0.05	0.09	1.10
	Conventional till wheat	575	0.12	0.64	4.81
1984–1990	Native grass	34	0.07	0.15	1.31
	Conventional till wheat	11,300	0.26	4.87	26.12
	No-till wheat	625	0.74	1.43	7.19

Figure 6 Mean annual nitrate-N concentration of ground water and dissolved and total P concentration runoff as a function of tillage management of watersheds in Oklahoma, USA. Data adapted from Sharpley AN and Smith SJ (1994) Wheat tillage and water quality in the Southern Plains. *Soil and Tillage Research* 30: 33–38.

attributed, in part, to greater soil water content under no-till compared with conventionally tilled wheat – a result of the increased residue cover enhancing percolation and soil water storage and reducing evaporation losses. The increase in dissolved P runoff can be attributed to leaching of P from crop residue and preferential transport of clay-sized particles under no-till compared with conventional tillage. In addition, such practices as strip cropping and contour planting reduce soil erosion potential and enhance infiltration.

These positive and negative impacts of conservation tillage practices on N and P loss potential should be considered in the development of sound nutrient management strategies. Clearly, a technically sound framework must be developed that recognizes critical sources of N and P export from agricultural watersheds so that optimal strategies at farm and watersheds scales can be implemented to best manage both N and P.

Permanent Vegetation

Keeping land in permanent cover, such as grass or cover crops, reduces the risk of runoff and erosion, increases infiltration,

and thereby minimizes the loss of N and P. Cover crops protect the soil surface from raindrop impact, improve infiltration relative to bare soil, and trap eroded soil particles (Sharpley and Smith, 1991). Where dissolved P transport is the primary concern, cover crops may reduce runoff and, consequently, runoff P load. Cover crops are unlikely to affect dissolved P concentrations in runoff, however. Kleinman *et al.* (2005a) found that cover crops reduced the total P concentration in springtime runoff to 36% of the dissolved P in runoff from conventional corn. But dissolved P concentration was not significantly different between cover crops and conventional corn because dissolved P was controlled by soil P content rather than by soil erosion.

Grassed waterways are designed to trap sediment and reduce channel erosion. In some cases, waterways are installed as cross-slope diversions to intercept runoff and reduce effective slope length. Chow *et al.* (1999) estimated that installation of grassed waterways and terraces in combination reduced annual soil erosion 20-fold in a New Brunswick, Canada potato field.

Riparian/Buffer Areas

Healthy riparian areas can reduce N and P export, increase wildlife numbers and diversity, and improve aquatic habitat. In addition to acting as physical buffers to sediment-bound nutrients, plant uptake captures N and P, resulting in short-term and long-term accumulations of nutrients in biomass (Groffman *et al.*, 1992; Peterjohn and Correll, 1984; Uusi-Kämpä *et al.*, 2000). Enhanced denitrification in riparian areas can reduce the loss of N from agricultural fields to stream corridors (Howarth *et al.*, 2000; Lowrance *et al.*, 1985).

The effectiveness of conservation buffers as a nutrient management practice can vary significantly. For instance, the route and depth of subsurface water flow paths through riparian areas can influence nutrient retention. Conservation buffers are most efficient when sheet flow occurs, rather than channelized flow, which often bypasses some of the retention mechanisms. Those areas must be managed carefully to realize their full retention and filtration capabilities.

Critical Source Area Management

Transport of N and P from agricultural watersheds depends to a large extent on the coincidence of source (soil, crop, and management) and transport factors (runoff, erosion, and proximity to water course or body). Source factors relate to watershed areas with high potential to contribute to N and P export. For N, amounts applied in excess of crop requirements can be leached from the soil profile by percolating water. For P, source areas are often spatially confined and limited in extent, generally reflecting soil P status and fertilizer and manure P inputs (Gburek and Sharpley, 1998; Pionke *et al.*, 2000).

Transport factors determine whether nutrient sources translate into nutrient losses. Nitrogen transport from agricultural land generally occurs on a watershed scale. Source factors tend, therefore, to govern the magnitude of N loss, whereas transport factors govern the time lag or delay caused by percolation through various soil layers. Nitrogen loss on cropland depends on the balance between N added (amount, timing, and form of N) and crop removal. The rate of N loss through leaching (transport factor) depends on soil properties (primarily texture and permeability) and the amount of water available to drain through the soil profile (rainfall and irrigation).

Phosphorus transport generally occurs from hydrologically active areas in a watershed where surface runoff contributing to streamflow is coincident with areas of high soil P (Gburek and Sharpley, 1998; Gburek *et al.*, 1996). For example, Pionke *et al.* (1996) reported that 90% of annual P exported ($0.63 \text{ kg kg}^{-1} \text{ ha}^{-1} \text{ year}^{-1}$) from a south central Pennsylvania watershed occurred during storm flow as surface runoff on saturated areas extending no more than 60 m from the stream channel and that itself accounted for only 10% of annual runoff. In contrast, only 20% of nitrate export was associated with storm events; the remaining 80% was exported in base-flow ($6 \text{ kg kg}^{-1} \text{ ha}^{-1} \text{ year}^{-1}$), which came from a larger recharge area of the watershed. Even in regions where subsurface flow pathways dominate, areas contributing P to drainage water appear to be restricted to soils with high soil P saturation and hydrologic connectivity to the drainage network. For example, Schoumans and Breeuwsma (1997) found that soils with high-P saturation contributed only 40% of the total P load,

whereas another 40% came from areas where the soils had only moderate P saturation but some degree of hydrological connectivity with the drainage network.

Water Quality Response to Land-Use Change

Critical sources areas of P on agricultural lands have increased due to the several decades of N-based manure applications that have resulted in the localized accumulation of P in soil. This stored P in soil and fluvial sediments is referred to as legacy P. Legacy P is particularly problematic because soil and sediment can serve as a long-term source of P to the overlying water column for several decades. Within freshwater ecosystems, legacy P can contribute to the external loading of rivers, lakes, and bays. Considering both soil and sediment sources, legacy P can mask reductions in P loss from agricultural lands with the implementation of BMPs.

In fluvial systems, the release of legacy P from deposited sediments can be influenced by the oxygen status of overlying waters, where reducing conditions favor the release of sediment-bound P. Also, the beneficial effects of BMPs on lower P inputs to stream and rivers will decrease P concentrations that trigger the release of P from sediments, masking the downstream benefits of BMPs on P fluxes. Finally, P-enriched sediments are resuspended during high flows.

Currently, a basin-level response to practices cannot be expected to be observed for some time. A better understanding of the spatial and temporal aspects of basin-level responses is needed, as well as on other scales at which response can occur in a more timely fashion. This would likely be smaller sub-watershed scales, where local water quality and quantity benefits may become evident more quickly (Bishop *et al.*, 2005) and that can enhance BMP adoption. Research on pre- and post-BMP implementation has indicated the value of small-scale monitoring and/or modeling of BMP effects at a local level (Chu *et al.*, 2004; Mostaghimi *et al.*, 2001). The modeling and monitoring study by Chu *et al.* (2004) indicated that climate variability plays a major role in compounding the short-term BMP effect in water quality improvements, even in small watersheds.

The importance of long-term monitoring in terms of assessing watershed response to conservation management is demonstrated by the Lake Erie Agricultural Systems for Environmental Quality (LEASEQ) Project (Richards *et al.*, 2002b, 2009). Phosphorus loads in two Ohio watersheds (Maumee and Sandusky River Watersheds) with major tributaries to Lake Erie, monitored since 1975 to determine the effect of adopting BMPs such as conservation tillage and nutrient management planning in predominantly row-crop agriculture (corn, soybean, and wheat), averaged an 8% increase in flow whereas the mean annual flow-weighted concentrations of suspended sediment, total P, and dissolved P decreased 23%, 44%, and 86%, respectively (Richards *et al.*, 2002a). Since 1995, annual flow-weighted concentrations of dissolved P have increased, whereas particulate (and total P) have continued to decline (Richards and Baker, 2010). The trend of increasing dissolved P and decreasing total P may be attributed to a combination of several factors: a change in the rainfall distribution pattern; a buildup at the soil surface with

conversion to no-till cropping; and increased application of fertilizer and manure, without incorporation in the fall and winter. Although this project did show that water quality can change in response to management change at a watershed scale, lessons learnt are broadly applicable to other watersheds.

Conclusions

In the past, separate strategies for P and N have been developed and implemented at farm or watershed scales. Because of differing biology, chemistry, and flow pathways of P and N in soil, these narrowly targeted strategies may lead to conflicting or suboptimal advice. As a result, the prevention of P and N loss from agricultural systems needs to focus on defining, targeting, and remediating source areas of P that combine high soil P levels with high erosion and surface runoff potentials and source areas of N that coincide with soils of high permeability. Thus, differing levels of management may be appropriate for different areas of a watershed. Overall, inputs in fertilizer and manures should be carefully matched with crop needs over the whole watershed. Short-term remediation of P loss should focus on critical source areas of P export where high soil P, P application, and zones of surface runoff and erosion coincide. However, lasting improvements in water quality can only be achieved by balancing system inputs and outputs of both P and N. Clearly, the management of agricultural nutrients involves a complex suite of options that must be customized to meet site-specific needs that are depicted in Figure 5. Even so, the long-term impacts have been and remain difficult to quantify.

A range of voluntary and regulatory measures can be used to encourage implementation of nutrient management strategies as part of conservation programs to protect soil and water resources. In general, the success of these measures relates to how well farmers can afford to implement new management strategies and the concomitant level of support or incentives for their adoption. In some instances, local or regional governmental controls may be necessary to enhance prompt adoption of practices that will have a positive influence on environmental outcomes.

In some areas, we cannot and should not expect that pristine waters are achievable with ever-increasing population densities and more intensive agricultural production systems to meet demand. The bottom line is that this may require either a reassessment of water-use designations and/or far-reaching societal commitment and support of agricultural system changes.

Glossary

Bush-fallow cropping system An agronomic system in which soil fertility is maintained by allowing native vegetation to regrow following several years of cropping.

Conservation tillage Tillage that reduces soil disruption in order to conserve organic matter and water and reduce erosion.

Ecosystem services The benefits people obtain from ecosystems.

Legumes Plants belonging to the family Leguminosae, many of whose members can form symbiotic associations with nitrogen-fixing bacteria.

Multifunctional cropping system An agronomic system that incorporates different combinations of

herbaceous crops, trees, and animals within a single farm unit.

Nitrogen fixation The transformation of atmospheric nitrogen into a form usable by plants.

Resource conservation The protection and enhancement of resources on which sustainability depends.

Rotation The sequence of crops grown in a single field.

Soil organic matter Material in soil containing organic carbon derived from the decomposition of mainly plant residue.

Trophic complexity The number and types of organisms that feed at different trophic levels within a community; also known as food web complexity.

Elements of Sustainability

Strictly defined, sustainability denotes any system capable of persisting. Because persistence depends on scale, *sustainable agriculture* is entirely scale dependent. An agricultural practice that is sustainable at the scale of an individual field may lack sustainability at the larger farm scale if the inputs required to maintain stable production eventually exceed the capacity of the farm to provide them. Likewise, farm-scale sustainability must be evaluated in the context of local and global regions, and global sustainability requires consideration of global output versus the long-term costs of that output and the ability of global resources to accept those costs.

Of course costs are not simply economic. They are also social and environmental: If a cropping system requires large inputs of nitrogen fertilizer that leak from the system to pollute groundwater drinking supplies and distant coastal fisheries, a system that may be sustainable at the field scale becomes nonsustainable at the farm and regional scale – even though the long-term supply of fertilizer is stable and the economic cost of fertilizer to the farmer is easily borne by higher grain production. Landscape models now being developed for farmer decision making on alternatives and for development extension planning are becoming increasingly available (Nassauer and Opdam, 2008).

Sustainable agriculture must therefore be defined not just in terms of its long-term economic productivity but also in terms of its environmental and social benefits and costs. Many of these costs are value-laden. For a society that values family farms, for example, sustainability must be evaluated in terms of the impact of farming practices on the social structure of rural communities: Do markets and policies favor large-scale producers to the exclusion of those who operate family farms and the rural communities in which they live? For a society that values biodiversity, sustainability must be evaluated in

terms of the impact of farming practices on wildlife health and habitat. These considerations take sustainability arguments into sometimes contentious territory because people have different social and cultural values. What is socially acceptable in one nation or to one segment of society may be socially unacceptable to another. These differences must be clearly defined when evaluating sustainability.

More specifically defined, sustainable agriculture is any suite of agronomic practices that are

- economically viable,
- environmentally safe, and
- socially acceptable.

These elements provide an operational definition of agricultural sustainability. There are many ways to blend them into an overarching definition, and many authors – and policymakers – have done so. In 1990, for example, the US Congress defined sustainable agriculture as “an integrated system of plant and animal production practices having a site-specific application that will, over the long term:

- satisfy human food and fiber needs,
- enhance environmental quality and the natural resource base on which the agricultural economy depends,
- make the most efficient use of nonrenewable resources and on-farm resources and integrate, where appropriate, natural biological cycles and controls,
- sustain the economic viability of farm operations, and
- enhance the quality of life for farmers and society as a whole.”

One should always keep in mind the subjective nature of these constructs, however, and that sustainability is a relative term. Although it may be difficult to foresee what ultimately will be sustainable, one can usually judge whether one set of practices is likely to be more sustainable than another at a societal scale.

Development of the Sustainability Concept

Sustainable agriculture as a descriptive term evolved toward common usage in the United States in the early 1980s as a mixture of concepts, ideas, values, and development direction that many believe is a vision for what agriculture should be. As with most visions, it has had strong impetus from a small group of critics of the conventional paradigm, notably Wes Jackson in his 1980 book *New Roots for Agriculture* (Jackson, 1980), and by 1984 the term was in widespread use. By 1991, the term had been fully “legitimized” as evidenced in the National Research Council’s (NRC) documentation of the many U.S. Department of Agriculture, university, and other programs in sustainable agriculture throughout the United States and abroad (NRC, 1991).

Many of the philosophical roots for sustainable agriculture that coalesced in the 1980s were traced from as far back as the Greek and Roman philosophers by Harwood (1990). The public agenda debate over sustainable agriculture of the 1980s embodied many of the older concepts but certainly not any one in its entirety. The notion of land ownership, cultivation, and personal connectedness to the land as a grounding for personal responsibility, morality, and sense of purpose can be found in the writings of English philosopher John Locke in the 1600s, those of Thomas Jefferson in the late 1700s, and recently in the poetry and books of Wendell Berry. Wes Jackson applied the concept to the 1990s in his book *Becoming Native to This Place* (Jackson, 1994), which focused on homecoming and on being native, i.e., developing an ecological literacy in a holistic sense, through being, living, and having personal experience with one’s ecosystem. The values in having a sense of place, a connectedness, have changed from an earlier focus on moral and political values; these values have nevertheless become a part of the vision.

The concepts of conservation and natural resource preservation are woven throughout sustainability, derived from the earlier work of Aldo Leopold and others. Louis Bromfield in *Malabar Farm* (Balantine, 1947) and the prolific writings of Edward Faulkner, beginning with *Plowman’s Folly* (Faulkner, 1943), had major impact. Faulkner’s work had a significant influence on both J.I. Rodale and his son, Robert, who carried the notion further to one of regenerative agriculture (Rodale, 1983), defined as an agriculture which not only maintains the natural resource base but also restores and increases its productive potential.

Organic, biodynamic, and the many schools of thought and broad literature surrounding these terms made major contributions to the sustainability debate. The “humus farming” school, with its focus on management of soil organic matter and the interconnectedness of soil health, plant health, and that of animals and humans, was a foundation for this philosophy. Several schools of organic practice originated in Europe and England, but the movement was popularized as organic agriculture in the United States by J.I. Rodale in his widely read book *Pay Dirt* (Rodale, 1945).

Each of these philosophical roots contained the notion of a holistic structure of agriculture – an interconnectedness between people, other living organisms, and the soil. Organic agriculture today continues a focus on “the living soil,” on optimizing the use of biological processes and on avoiding the

use of synthetic chemicals and fertilizers. Most sustainable advocates agree with a biological focus and hope to reduce but not necessarily eliminate chemical use.

Major impetus for the new vision also evolved from the 1960s era of intense agricultural development. The magnitude of the chemical revolution with its newly available pesticides, herbicides, and fungicides plus the availability of concentrated, more easily handled fertilizers very much narrowed the global agricultural development focus to the high productivity of major cereal crops. The very real specter of massive starvation in China and hunger and food deficits in India, Bangladesh, and many other countries drove the agricultural development of the 1960s. The low cost of oil and gas and prosperous northern economies all combined for infrastructure development, high agricultural inputs, and the well-known green revolution of this period.

A backlash of environmental impact, embodied in Rachel Carson’s *Silent Spring* (Carson, 1962), the oil crisis of the early 1970s, and concern over a growing gap between rich and poor people and nations all set the stage for the new vision. The senescence and decline of rural communities in the United States during the 1970s and 1980s added urgency to the social dimensions of agriculture. The narrowness and focus of the development debate of the 1960s set the stage for a new, broader vision that included revisiting the old and much introspection amid assurances of decreasing real food prices and near-term global food security.

The 1980s and early 1990s produced a plethora of sustainable agriculture development writings. *Future Horizons: Recent Literature in Sustainable Agriculture* (Hegyes and Francis, 1997) is an excellent review of this broad literature. The terms “low-input sustainable” and “alternative agriculture” appeared frequently and are still used by many non-American authors, particularly with reference to organic production systems. The *American Journal of Alternative Agriculture* was founded in the mid-1980s, and in 1989 the NRC’s report, *Alternative Agriculture* (NRC, 1989) brought the name “alternative agriculture” to prominence. Alternative agriculture was defined, in these sources, as any food or fiber production that has:

- a more thorough incorporation of natural processes;
- reduced use of off-farm inputs, with less harm to the environment and consumers;
- a more productive use of the biological and genetic potential of plants and animals;
- a better match between cropping patterns and the physical capacity of lands; and
- an improved emphasis on conservation of soil, water, energy, and biological resources.

Alternative agriculture is not synonymous with organic agriculture (which completely avoids synthetic chemical inputs), but they share many of the same farm management practices and approaches.

The 1980s and 1990s led us from a primary focus on engineering and chemistry in agriculture toward a greater emphasis on biology – from an age of “alchemy” to the age of “algeny” (Rifkin, 1983). The adoption of the term “agroecology” signaled a reemphasized trend in holistic thinking and analysis. A shift in emphasis within the field of ecological

science toward managed ecosystems in the late 1980s added significant perspective. Entomologists, agronomists, and other scientists began to use an ecological, process-oriented approach. Stephen Gliessman's *Agroecology: Ecological Processes in Sustainable Agriculture* (Gliessman, 1998) is an example of one book on this topic. The infusion of ecological thinking has added clarity to our understanding of overlays of subsystems, of spatial hierarchies, and of how complexity makes up an agricultural ecosystem. It has added to the understanding of multiple functions of an agricultural system and to the notion of ecosystem services. Most importantly, agroecology has taken the analysis of sustainability to a process level of understanding that allows us to understand gradients of change in production systems across time and space.

Giving greater voice in development direction to farmers has been another significant dimension in sustainable agriculture. It was very apparent that much, if not most, of alternative agriculture had originated with farmers. Philosophical direction had been heavily influenced by farmer-writers. The resurgence of on-farm research in the developing world of the 1970s (Harwood, 1979) was followed by similar emphasis with farmer collaborators in the United States in the 1980s and 1990s. Farmers have been increasingly invited to serve on steering committees and research grant award committees for sustainable agriculture projects.

Farm family well-being and that of their rural communities has been another major area of merger and inclusion in the sustainability vision. The many links and interdependencies between human and community development and sustainable agriculture are being considered in the structure and design of food systems. In 1986, Dahlberg, presented a comprehensive and thought-provoking collection of writings on social, economic, and structural issues (Dahlberg, 1986). The importance of farm size, community interaction, and the global structure of the food system is seen to be critical to both social and economic well-being. Heffernan (1997) forcefully makes the point that with globalization of capital markets and the resulting centralization of control and ownership (of both input supply and product handling and processing) have come a reduction in market competition, a shift in the balance of economic power away from the producer, and a replacement of farm-level production instability with greater macroeconomic instability in the marketplace. Much of the current literature on the social dimensions of sustainable agriculture is found in *Agriculture and Human Values*, the Journal of the Agriculture, Food, and Human Values Society.

Economic dimensions of sustainable agriculture have been typically associated with whole-farm studies comparing organic with "conventional" farms in the late 1970s, exemplified by paired comparison studies in the Midwest (e.g., Lockeretz et al., 1981). Other, single-farm studies have been reported, such as in the case studies of the NRC's report *Alternative Agriculture* (NRC, 1989). Most of these studies have shown organic farms, in most years, to be as profitable as conventional farms. Most of the sustainable agricultural production research of the past two decades has focused on comparisons of crop rotations and use of cover crops and other systems component practices.

There has been a growing crescendo of voices critical of the failure to account for the side effects, the "external costs" of

conventional agriculture (e.g., Roberston and Swinton, 2005). These external factors impact communities, the environment, and human health. There is increasing criticism of the emerging structure, which includes farm scale, the patterns of movement of food, and the corporate concentration of input supply and processing on a global scale. A significant component of the sustainable agriculture debate concerns the desirability of some portion of foods being of local origin, with the size of that portion related to location and community development status (Shuman, 1998; Harwood, 1998).

Scientific projections for the required incremental and transformative changes needed in US agriculture in the coming decades are based on the integration of biological, social and economic interactions across a range of scales to provide the necessary increase in resource use efficiency to supply the multitude of products and services expected by society. Robustness at varying scales, based on productivity, resilience and resistance to shock must be increasingly incorporated into systems design (NRC, 2010).

Long-standing schools of thought and practice in agriculture, influenced by changes in science and technology and in food system structure, have thus provided much of the content of the present-day sustainable agriculture agenda or vision. The amalgam of ideas and component factors has provided an extremely rich background from which development direction can be modified. The breadth of the agenda and the level of dissatisfaction with the current system point to a very major underlying problem of the global, monetarily driven process that is directing and fueling current change.

Most of the sustainable agricultural debate concerns differences in goals and in ethical and value dimensions between farmers, agriculture as a sector, and national, international, and global interests as pointed out so clearly by Dahlberg (1985). Many of the resources used and managed by agriculture and many of the services and outputs from agriculture that are critical to ecological and human well-being lie outside the monetary process that is currently driving global agriculture. If the marketplace does not put value on those dimensions and the political process either cannot or will not value them, there is a high level of disarray. Much of today's sustainable agriculture debate revolves around these value differences. Many of these sustainability issues are deeply imbedded in the current public debate over genetically modified organisms.

Indicators of Sustainability

What agricultural practices are sustainable? This is an area of intensive research. Sustainable practices must meet the three criteria defined in *Elements of Sustainability*: They must be economically viable, environmentally safe, and socially acceptable. There is no single prescription for sustainability; sustainable practices will vary by cropping system, local environment, and socioeconomic system. Nonetheless, emerging research results suggest that locally sustainable systems tend to be more resource conservative than less sustainable systems and tend to rely less on external subsidies and more on internal ecosystem services.

Resource Conservation

Resource conservation means that those resources on which sustainability depends are conserved and even enhanced by agronomic management. Soil organic matter is a good example of an ecosystem resource that is easily reduced without effective management. Soil organic matter declines rapidly in almost all cropping systems following initial cultivation – typically to 40–60% of original values within a few decades. However, soil organic matter is a valuable resource, providing habitat and energy for soil organisms, a soil structure favorable for plant growth and water retention, and a chemical structure favorable for nutrient retention (Robertson and Grandy, 2006).

The loss of soil organic matter is often associated with a need for greater external inputs. Cropping practices that conserve or enhance soil organic matter buildup will invariably enhance the environmental and often the economic sustainability of cropping systems. Crops grown in high-organic matter soils have a better water and nutrient environment than similar crops grown in soils that are depleted in organic matter, and thus they may require fewer external inputs for the same productivity. Additionally, less soil erosion and lower runoff from high-organic matter soils better protects downstream environments from agronomic impact. Therefore, cropping practices that conserve soil organic matter can be considered more sustainable than those that do not.

Often, however, there are trade-offs that require any specific conservation effort to be evaluated in the overall context of sustainability. For example, conservation tillage typically slows or stops soil organic matter loss and thus can be considered a resource-conserving, sustainable cropping practice. However, tillage controls weeds in cropping systems, and in the absence of tillage weed control is typically achieved with herbicides, which have environmental and economic costs different from those of tillage. Is the maintenance of soil organic matter as sustainable in light of a more intensive reliance on herbicides? Ideally, such trade-offs can be minimized. For example, winter cover cropping can also reduce soil organic matter loss and additionally can reduce nitrate leaching and suppress weeds, without the need for additional herbicide (Snapp *et al.*, 2005). Each cropping practice must be evaluated in a whole-system context to adequately evaluate its contribution to a system's sustainability.

Ecosystem Services

Ecosystem services are the benefits people obtain from ecosystems, often categorized as provisioning, regulating, cultural, and supporting (Millennium Ecosystem Assessment, 2003). Unmanaged systems provide such services as a matter of course. Farms are historically valued for their provisioning services – food, fuel, and fiber production – but in fact provide a whole host of other services ranging from pollination and disease regulation (regulating services) to soil and nutrient conservation (supporting services) to aesthetic amenities and a sense of place (cultural services) (Swinton *et al.*, 2007). Ecosystem services are integral to the functioning of healthy ecosystems.

In modern cropping systems many services provided by the original ecosystem before its conversion to agriculture have been suppressed or ignored in favor of services provided by external inputs. In a nitrogen-poor native ecosystem, for example, biological nitrogen fixation by native legumes such as clover (*Trifolium* spp.) might be a principal source of fixed nitrogen; modern cropping systems instead rely almost exclusively on industrially fixed nitrogen provided as inorganic fertilizer (Robertson and Vitousek, 2009). In an unmanaged system, insect herbivory is suppressed largely by trophic and structural complexity that enables insect and vertebrate predators to keep plant pests at bay. In most modern systems insect pests are controlled with insecticides, which also kill insect predators. Managing a cropping system with legumes or with greater plant diversity (either within fields or in the landscape) would allow the ecosystem to provide more of the services now provided via external inputs. Legume cover crops can reduce the need for external nitrogen, and greater plant diversity can provide the structural complexity and refugia needed to support predator populations in otherwise mono-specific landscapes.

Just as for practices intended to enhance resource conservation, practices established to reintroduce or enhance existing ecosystem services need to be evaluated on the basis of their total net contribution to sustainability. Although nitrogen fixation by legumes can lower the need for fertilizer inputs and benefit soil organic matter buildup as well as provide winter habitat for predaceous insects, there is little evidence that legume-fixed nitrogen is conserved more tightly than fertilizer-derived nitrogen. Thus, there may be no downstream environmental benefit associated with this ecosystem service. Likewise, animal manure produced on-farm and recycled back to the field may be less conserved than fertilizer nitrogen if the manure is added at a time of low plant nutrient demand. Ongoing research is helping to identify ways in which management can add ecosystem services that both enhance resource availability and reduce the environmental costs of agriculture. At the societal scale there is ongoing debate on how to value services provided by farms to their neighboring communities (Robertson and Swinton, 2005). Should farmers be compensated for managing their land in ways that provide services to local, regional, and national communities? Such payments occur on a small scale in some parts of Canada, the United States, and Europe today.

Examples of Sustainable Cropping Systems

Bush-Fallow Rotation Systems

Perhaps the best documented example of a locally sustainable cropping system is the bush-fallow rotation, also known as swidden and slash and burn agriculture, indigenous to many cultures before the advent of continuous cropping systems several hundred years ago, and still evident in the humid tropics today. In the absence of population change, the bush-fallow system allows a tract of forest or savanna to provide food with few subsidies other than human labor.

In these systems, a small section of native vegetation is cut and cropped. Crop nutrient needs are met by the

decomposition of soil organic matter and perhaps by leguminous crops. Sufficient pest protection is provided by crop rotation, complex crop mixtures, and the proximity of fields to native vegetation. Weed suppression is performed by hand.

Once soil nutrients are depleted to levels that significantly compromise crop productivity, the plot is abandoned to “bush fallow” and another plot is cleared from native vegetation and cropped. Meanwhile, the now-abandoned but newly fallowed plot is undergoing secondary succession with attendant recovery of soil nutrient stores. By the time several more plots have been sequentially cut, cropped, and fallowed, the original plot will have recovered much of its original fertility and be ready to be cleared and cropped again.

Such agronomic systems are sustainable indefinitely as long as each cropped area is allowed sufficient time to recover its original fertility. However, when land becomes scarce because of development or population growth or both, the system can quickly fail. Native vegetation brought out of fallow too quickly will provide soil fertility for only a portion of the former cropping periods, so the crop portion of the rotation will either be shorter or yield less, forcing more of the native vegetation to be brought out of fallow earlier than planned in order to feed a growing population. Eventually, little native fallow will remain and crops will be grown continuously on soils that now lack much of their former fertility. One of today's greatest agronomic challenges is providing nitrogen and phosphorus to cropping systems that until recently have been in bush-fallow rotations, especially in sub-Saharan Africa where fertilizer is largely unavailable and most food is grown on small holdings of a few hectares. The maintenance of soil quality and adequate levels of soil organic matter to provide it are major concerns of tropical agronomists. Promising recent advances include the incorporation of more biodiverse rotations with modest fertilizer inputs to provide services elsewhere provided by intensive external inputs (Snapp *et al.*, 2010).

Multifunctional Agriculture

The successor to simple bush-fallow systems is mixed farming systems that have several production enterprises of different herbaceous crops, trees, animals, or combinations of crops and animals. In less developed or unstable economies requiring a high level of local, community, and farm family self-reliance, the production of a wide array of goods was primarily to meet family and local market needs and to ensure a year-round supply of food, fuel, and building materials. Farm and landscape-level diversity optimized stability within local environments and increased the resiliency of the system to a wide variety of disturbances. The diversity of land use provided a wide range of ecosystem services, including precipitation management, groundwater recharge, wildlife habitat, an environment usually conducive to adequate pest-predator balance, and some mitigation of harsh climatic conditions. The mixed plant community provided shade, wind protection, privacy, and many other, often seasonal, assorted products and services. This range of outputs has recently been termed the multifunctional character of agricultural land (Food and Agriculture Organization, 1999; Boody *et al.*, 2005) shown in Figure 1.

Figure 1 Changes in the purposeful development of the multifunctional character of agricultural land (MFCAL) as markets evolve (adapted from Fresco L, personal communication).

As infrastructure and markets develop, the need for a broad range of products and services decreases. When the costs of adverse environmental impacts such as groundwater contamination are not internalized, or when farmers are not rewarded for ecosystem services that their farms provide to the community or region, they do not include such values in their farm enterprise unless they are motivated and willing to make an altruistic contribution. Many farmers, in fact, do this now, but ultimately the more narrowly focused economic marketplace rules. Today's farms in highly developed economies frequently have a level of product and land use specialization that is well below an acceptable standard for long-term environmental and resource sustainability (Figure 1, Box B). In other words, the production base, the environment, and its ecosystem have not been stabilized and are being degraded. With continued market evolution, farmers may be increasingly compensated for the full range of ecosystem services as well as actual product output that they provide (Shuman, 1998; Soule and Piper, 1992; Robertson and Swinton, 2005) (Figure 1, Box C).

A more immediate incentive is to add crops and/or livestock to provide integration efficiencies. These efficiencies include the increase in yield of one crop following another, the savings in nutrient inputs, or the reduction in pest control costs (Table 1).

An increasing amount of information on the efficiencies of specific technologies for integration is becoming available in the scientific literature. The reduction in input requirements is often a key part. There is less direct research information on the relationship of many of these practices for mitigating environmental harm. An exception is the wealth of data on reduced soil erosion as a result of reduced or zero tillage. Currently, the predictive models of loss of pesticides, nutrients, or crop or animal residues are rudimentary. Direct

Table 1 Michigan maize, soybean, and wheat rotation efficiencies

System, advantages
Maize after beans 30 kg ha ⁻¹ nitrogen credit No rootworm scouting or control costs 6–10% yield advantage
Maize after soybeans dry beans wheat (Michigan, second, third year of rotation) No nitrogen credit (since maize follows wheat) No rootworm control costs Window for perennial weed control (either mechanical or chemical) Greater than 10% yield advantage (because of the preceding bean/wheat sequence)
Maize after wheat plus frost-seeded clover 40 kg ha ⁻¹ nitrogen credit (60–70 kg N ha ⁻¹ with presidedress nitrogen test) No rootworm control costs At least 15% yield advantage 30–50% yield advantage if the farm is organic, where maize-after-maize is not advisable

measurements of loss from alternative rotations and use of cover crops are very difficult, expensive, and location specific. These rotation and cover crop practices are widely acknowledged as fundamental to sustainability. Their efficiencies are being quantified with respect to yield, input reduction, and soil quality and the prevention of soil loss. Michigan data show, for instance, that wheat in rotation loses less than 20 kg N ha⁻¹ year⁻¹ via groundwater leaching. Well-fertilized continuous corn averages 50 kg N ha⁻¹ year⁻¹. Most U.S. farmers use at least a two-crop rotation.

Animal integration in crop systems is declining in the United States. Poultry and turkeys are increasingly produced in specialized production facilities not located on the farms where their feed is produced. They are usually located in areas where agricultural land is available for manure application, often on a contract “disposal” basis. The level of crop or animal diversity that is appropriate on a farm to balance the market forces for specialization with the need for biological efficiency and ecosystem maintenance is very situation specific. As enterprise integration increases with an effective level of appropriate technologies and their effective management (Figure 2, technology T₂), agricultural output can be maintained at a much higher level for a given amount of ecosystem disturbance. In other words, sustainable agriculture can maintain productivity at a much lower level of ecosystem disturbance. Very large-scale operations tend to have less diversity, in part because of the greater difficulty of managing diverse enterprises. Crop and animal management requires numerous and often frequent decisions to be made as conditions change that are often stimulated by visual, difficult to measure changes. The frequent presence and sensitivity of the manager, the experience in production management, and the ability to make decisions place limits on the scale of highly diversified operations. Every farm owner experiences this tension.

On a global scale, under conditions of high population density, small farms, and the need for producing a wide array of products in often marginal production environments, a very

Figure 2 Effect of technology selection on the relationship between agricultural production and ecosystem maintenance. ED, environmental disturbances; T₁, inappropriate technology; T₂, more appropriate technology; P₁, agricultural production with technology T₁; P₂, agricultural production with technology T₂ (adapted from NRC (1993)).

Figure 3 Combinations of enterprises in mixed farming systems (redrawn from Serrão EAS and Homma AKA (1993) Brazil. In: National Research Council. (eds.) *Sustainable Agriculture and the Environment in the Humid Tropics*, pp. 265–351. Washington, DC: National Academy Press, with permission from Dr. Scott).

diverse type of farm enterprise mix is common. Trees become a very important part of farm productivity in the higher rainfall areas where they are a part of the native vegetation. Animals are more often than not a part of the enterprise because they consume crop residues and add significantly to overall productivity (Figure 3). In most developing countries there is very little area of undisturbed forest, and in only a few in which large tracts of land remain is there cattle only on farms. In the humid tropics the mixture of crops, trees, and animals

(agrisilvo-pastoral systems) represent the great majority of farms. Where human population is relatively high ($> 300\text{--}500$ persons per square kilometer) in rural areas, if there is poverty combined with modest levels of rainfall (less than 1500 mm year^{-1}) and/or cool temperatures for part of the year, fuel for cooking and heating becomes a problem. Resource degradation and loss of production potential often occur as the standing stocks of carbon (particularly in trees) and eventually the soil carbon stocks are reduced as crop and animal residues are burned. The system rapidly loses crop nutrient holding and recycling capacity, and its ability to intercept and retain rainfall decreases. Most developing country mixed farms have a larger portion of cash grain crops.

Many countries in eastern Africa (Kenya, Ethiopia, Rwanda, Tanzania, and Uganda) have these exacting conditions. Rural well-being depends on small farms (between 0.5 and 1.5 ha) supporting families by providing food, fuel, building materials and cash income (Figure 4). Ruminant animals (often dairy cows or dairy goats) are a key part of that production. The productivity of the animals and their welfare through the dry season depends on fodder trees and other perennials, which are nearly always mixed into the landscape in intricate patterns. There is always a high diversity of food and fodder crop species, which protect the soil from erosion in sometimes heavy rainstorms and give the systems overall stability and resilience. Improved varieties of both trees and crop plants and improved animal breeds are critical to ongoing improvements (Pye-Smith, 2010).

Figure 4 In Kenya's densely populated Central Province, multi-functional agriculture includes grain and tree crops as well as ruminant animals such as dairy cows that depend on trees for fodder (credit: ICRAF/C. Pye-Smith).

Conclusions

Our global food and fiber production systems are undergoing an enormous transformation, driven by rapid advances in the sciences of biotechnology, engineering, and food processing and chemistry. The increasing centralization in the manufacture of agricultural inputs and in the collection and processing of food is causing huge economic and social change. Many social and political values are being challenged. The global marketplace forces product uniformity and the geographical concentration of its production are driving farmers toward a level of specialization that results in farms with much less diverse crop and animal enterprises on the landscape than that desirable for the maintenance of many ecosystem services. Markets have not yet matured to adequately value these services, especially those that affect environmental quality, nor in most places have governments established disincentives in order to protect them. The greatest challenge to sustainability, with its many economic, environmental, and social dimensions, is the lack of public awareness, vision, and will to implement necessary changes. In some cases, research is needed to clarify the value of alternative strategies and to provide additional options for sustainable management.

In many if not most places food is not being produced sustainably, i.e., in a manner that is economically viable, environmentally benign, and socially acceptable to many who are affected by its production. On the other hand, new research is showing that sustainable cropping systems can be designed to operate effectively, using ecological knowledge to substitute for some of the management options now provided by external inputs, and in a way that has a less adverse environmental and social impact than conventional management. A better understanding of agricultural ecosystems and the services they provide, coupled with new technology, may provide the advances needed to feed – sustainably – a burgeoning global population in the decades to come.

Glossary

Agroecosystem A simplified natural ecosystem subjected to exploitation for purposes of food and fiber production.

Biodiversity Diversity of microbial, animal, and plant species in an ecosystem that performs distinct ecological functions and services.

Ethnoecology Study of the various forms of traditional environmental knowledge that are characteristic of specific ethnic groups and that translate into natural resource management.

Polyculture Intensive growing of two or more crops either simultaneously or in sequence on the same piece of land.

Sustainable agriculture Form of agriculture that is environmentally sound, culturally sensitive, socially acceptable, and economically viable.

Traditional agriculture Indigenous form of ecologically based agriculture resulting from the coevolution of local cultural and environmental systems.

Introduction

One of the salient features of traditional farming systems throughout the developing world is their high degree of biodiversity. These traditional systems have emerged over centuries of cultural and biological evolution and represent the accumulated experiences of indigenous farmers interacting with the environment without access to external inputs, capital, or modern scientific knowledge (Chang, 1977; Grigg, 1974). Using inventive self-reliance, experiential knowledge, and locally available resources, traditional farmers have often developed farming systems that generate sustained yields (Harwood, 1979). In Latin America alone, more than two and a half million hectares are under traditional agriculture in the form of raised fields, polycultures, and agro-forestry systems, documenting the successful adaptation of these farming practices to difficult environments (Altieri, 1991).

Many of these traditional agroecosystems, still found throughout the Andes, Meso-America, and the lowland tropics, constitute major *in situ* repositories of both crop and wild plant germplasm. From an agroecological perspective, these agroecosystems can be seen as a continuum of integrated farming units and natural or semi-natural ecosystems where plant gathering and crop production are actively pursued. Plant resources are directly dependent on management by human groups; thus, both species and genetic diversity have evolved in part under the influence of farming practices shaped by particular cultures and the forms of sophisticated knowledge they represent (Nabhan, 1983).

Perhaps the key to understanding how traditional farmers maintain, preserve, and manage biodiversity is to recognize the complexity of their production systems. Today, it is widely accepted that indigenous knowledge is a powerful resource in its own right and complementary to knowledge available from Western scientific sources. Therefore, in studying such systems, it is not possible to separate the study of agricultural biodiversity from the study of the culture that nurtures it.

This article explains the features of the biodiversity inherent in traditional agroecosystems, and the ways in which farmers apply local knowledge to manage such biodiversity to satisfy subsistence needs and to obtain ecological services. Traditional agriculture is rapidly disappearing in the face of major social, political, and economic changes. The conservation and management of this agrobiodiversity will be possible only if they are linked to the preservation of the cultural diversity and economic viability of the local farming populations.

Biodiversity Features of Traditional Agroecosystems

Traditional farming systems commonly support a high degree of plant diversity in the form of polycultures and/or agro-forestry patterns (Chang, 1977; Clawson, 1985). This strategy of minimizing risk by planting several species and varieties of crops stabilizes yields over the long term, promotes diet diversity, and maximizes returns even with low levels of technology and limited resources (Harwood, 1979). Such biodiverse farms are endowed with nutrient-enriching plants, insect predators, pollinators, nitrogen-fixing and nitrogen-decomposing bacteria, and a variety of other organisms that perform various beneficial ecological functions.

Traditional multiple-cropping systems provide as much as 15–20 percent of the world food supply (Francis, 1986). Polycultures constitute at least 80 percent of the cultivated area in West Africa and predominate in other parts of Africa as well (Norman, 1979). At the same time, much of the production of staple crops in the Latin American tropics occurs in polycultures. More than 40 percent of the cassava, 60 percent of the maize, and 80 percent of the beans in the region grow in mixtures with each other or other crops (Francis, 1986). Polycultures are also very common in parts of Asia where upland rice, sorghum, millet, maize, and irrigated wheat are the staple crops. Lowland (flooded) rice is generally grown as a monoculture, but in some areas of Southeast Asia farmers

build raised beds to produce dryland crops amid strips of rice (Beets, 1982).

Tropical agroecosystems composed of agricultural and fallow fields, complex home gardens, and agroforestry plots commonly contain well over 100 plant species per field, and these are used as construction materials, firewood, tools, medicines, livestock feed, and human food. Examples include multiple-use agroforestry systems managed by the Huastecs and Lacandones in Mexico, the Bora and Kayapó Indians in the Amazon River basin, and many other ethnic groups who incorporate trees into their production systems (Wilken, 1977).

In the Latin American tropics, home gardens are a highly efficient form of land use, incorporating a variety of crops with different growth habits. The result is a structure similar to that of tropical forests, with diverse species and a layered physical configuration (Denevan *et al.*, 1984). In Mexico, for example, Huastec Indians manage a number of fields, gardens, and forest plots that may harbor a total of about 300 species. Small areas around their houses commonly average 80–125 useful plant species, mostly native and medicinal plants. Huastec management of the noncrop vegetation in these complex farm systems has influenced the evolution of individual plants and the distribution and composition of the crop and noncrop communities.

In these “forestlike” agricultural systems, nutrient cycles are tight and closed. In traditional shaded coffee plantations (where *Inga* and *Erythrina* are common tree species), the total nitrogen input from the decomposition of shade tree leaves, as well as from litter and symbiotic fixation, can be well over ten times higher than the net nitrogen output in the coffee harvest, which usually averages 20 kg/ha/yr. Clearly, the system amply compensates for the nitrogen loss by harvest with a subsidy from the shade trees. In Mexico, farmers encourage the growth of native leguminous trees in cultivated fields (Wilken, 1977). From Puebla and Tehuacán south through Oaxaca, farms with light to moderately dense stands of mesquite (*Prosopis* spp.), guaje (*Leucaena esculenta*), and guamuchil (*Pithecellobium* spp.) are a familiar sight. Stand density varies from fields with only a few trees to virtual forests with crops planted beneath them. A slightly different practice is found near Ostuncalco, Guatemala, where rigorously pruned sauco (*Sambucus mexicana*) stumps dot maize and potato fields. Sauco leaves and small branches are removed annually, scattered around individual crop plants, and then chopped and interred with broad hoes. Local farmers claim that crop quality and yields in the sandy volcanic soils of this region depend on the annual application of this method (Wilken, 1977).

Many traditional agroecosystems are located in centers of crop diversity, and thus contain populations of variable and adapted landraces as well as wild and weedy relatives of crops (Harlan, 1976). Clawson (1985) described several systems in which tropical farmers plant multiple varieties of each crop; this practice supports both intraspecific and interspecific diversity, and also enhances harvest security. For example, in the Andes, farmers cultivate as many as 50 potato varieties in their fields (Brush, 1982). Similarly, in Thailand and Indonesia, farmers maintain a diversity of rice varieties adapted to a wide range of environmental conditions, and they regularly

exchange seeds with each other (Grigg, 1974). The resulting genetic diversity heightens resistance to diseases that attack particular strains of the crop and enables farmers to exploit different microclimates and to derive multiple nutritional and other uses from the genetic variation among the species.

Many plants within or around traditional cropping systems are wild or weedy relatives of crop plants. In fact, many farmers “sponsor” certain weeds in or around their fields that may have positive effects on soil and crops, or that serve as food, medicines, ceremonial items, teas, soil improvers, or pest repellents. In the Mexican Sierras, the Tarahumara Indians depend on edible weed seedlings or “quelites” (e.g., *Amaranthus*, *Chenopodium*, *Brassica*) in the early season from April through July, a critical period before crops mature from August through October. Weeds also serve as alternative food supplies in seasons when maize or other crops are destroyed by frequent hail storms (Bye, 1981). In barley fields, it is common for Tlaxcalan farmers to maintain *Solanum mozinianum* at levels up to 4500 plants/ha; this yields about 1300 kg of fruit, a significant contribution to agricultural subsistence (Altieri and Trujillo, 1987).

Farmers also derive other benefits from weeds, such as increased gene flow between crops and their relatives. In Mexico, when the wind pollinates maize, natural crosses occur with wild teosinte growing in the field borders, resulting in hybrid plants. Certain weeds are used directly to enhance the biological control of insect pests, as many flowering weeds attract predators and parasites of pests to their pollen and nectar. Other farmers allow weeds such as goosegrass (*Eleusine indica*) in bean fields to repel *Empoasca* leafhoppers, or wild *Lupinus* as a trap plant for the pestiferous scarab beetle (*Macrodactylus* sp.), which otherwise would attack corn (Altieri, 1993).

However, diversity is maintained not only within a cultivated area. Many farmers maintain natural vegetation adjacent to their fields, and thus obtain a significant portion of their subsistence requirements through gathering, fishing, and hunting in habitats that surround their agricultural plots. For the P’urhepecha Indians who live around Lake Pátzcuaro in Mexico, gathering is part of a complex subsistence pattern that is based on multiple uses of their natural resources. These people use at least 224 species of native and naturalized vascular plants for dietary, medicinal, household, and fuel needs (Caballero and Mapes, 1985).

Depending on the level of biodiversity of closely adjacent ecosystems, farmers accrue a variety of ecological services from surrounding natural vegetation. For example, in western Guatemala, the indigenous flora of the higher-elevation forests provide valuable native plants that serve as a source of organic matter to fertilize marginal soils, for each year farmers collect leaf litter from nearby forests and spread it over intensively cropped vegetable plots to improve tilth and water retention. Some farmers may apply as much as 40 metric tons of litter per hectare each year; rough calculations indicate that a hectare of cropped land requires the litter production of 10 ha of regularly harvested forest (Wilken, 1977).

Clearly, traditional agricultural production commonly encompasses the multiple uses of both natural and artificial ecosystems, where crop production plots and adjacent habitats are often integrated into a single agroecosystem.

The Complex Nature of Traditional Farmers' Knowledge

Ethnoecology is the study of the natural world knowledge systems of indigenous ethnic people. This knowledge has many dimensions, including linguistics, botany, zoology, craft skills, and agriculture, and is derived from the direct interaction between humans and their environment. In such a system, cognition and perception select the most adaptive and useful environmental information, and this "successful" knowledge is preserved from generation to generation through oral or experimental means. Indigenous peoples' knowledge about soils, climates, vegetation, animals, and ecosystems usually results in multidimensional productive strategies (i.e., the use of multiple ecosystems with multiple species), and these strategies generate (within certain ecological and technical limits) the food self-sufficiency of farmers in a region (Netting, 1993).

Captivated by the ecological intricacies of these traditional agricultural systems, many scientists are now beginning to show interest in them. As scientists search for ways to remedy the deficiencies of modern agriculture, they recognize that indigenous farmers' knowledge may hold vital information for the future of world agriculture. After centuries of cultural and biological evolution, these farmers have developed locally adapted, complex farming systems that have helped them to sustainably manage a variety of environments and to meet their subsistence needs, without depending on modern agricultural technologies.

For many agricultural scientists, four aspects of these traditional knowledge systems are relevant: knowledge of the environment, folk taxonomies, knowledge of farming practices, and the experimental nature of traditional knowledge (Altieri, 1987).

Knowledge of the Environment

Indigenous knowledge about the physical environment is often very detailed. Many farmers have developed traditional calendars to control the scheduling of agricultural activities, and many sow according to the phase of the moon, believing that there are lunar phases of rainfall. They also cope with climatic seasonality by utilizing weather indicators based on the phenologies of local vegetation.

Soil types, degrees of soil fertility, and land-use categories are also discriminated in detail. Soil types are commonly distinguished by color, texture, and sometimes taste. Shifting cultivators usually classify their soils based on vegetation cover. In general, peasants identify soil types based on the nature of the peasant's relationship to the land (Williams and Ortiz-Solario, 1981). Aztec soil classification systems were very complex, recognizing more than two dozen soil types identified by origin, color, texture, smell, consistency, and organic content. These soils were also ranked according to agricultural potential, which was used in both land-value evaluations and rural census. Today, Andean peasants in Coporaque, Peru, recognize four main soil classes, where each class has specific characteristics matching the most adequate cropping system (Brush, 1982).

Biological Folk Taxonomies

Many complex knowledge systems that are used by indigenous people to group together plants and animals have been well documented (Berlin *et al.*, 1973). The traditional name of a plant or animal usually reveals that organism's taxonomic status, and researchers have found that, in general, there is a good correlation between folk taxa and scientific taxa.

The classification of animals, especially insects and birds, is widespread among indigenous farmers. Insects and related arthropods have major roles as crop pests, as causes of disease, as food, and as medicinal products, in addition to their importance in local myth and folklore. In many regions of the world, agricultural pests are tolerated because they also constitute agricultural products; that is, traditional agriculturalists may consume plants and animals that would otherwise be considered pests (Brokensha *et al.*, 1980).

Ethnobotanies are the most commonly documented folk taxonomies (Alcorn, 1984). The ethnobotanical knowledge of certain campesinos in Mexico is so elaborate that the Tzeltal, P'urepecha, and Yucatan Mayans can recognize more than 1200, 900, and 500 plant species, respectively (Toledo *et al.*, 1985). Similarly, !ko bushwomen in Botswana were able to identify 206 out of 211 plants collected by researchers (Chambers, 1983), while Hanunoo swidden cultivators in the Philippines could distinguish over 1600 plant species (Grigg, 1974).

Knowledge of Farming Practices

As more scientific research is conducted, many of the traditional farming practices once regarded as primitive or misguided are being recognized as sophisticated and appropriate. For example, when confronted with specific problems of slope, flooding, drought, pests, diseases, or low soil fertility, small farmers throughout the world have developed unique management systems aimed at overcoming these constraints (Klee, 1980). In general, traditional agriculturalists have adjusted to environmental constraints by concentrating on a few characteristics and processes that incorporate the following structural and functional elements (Gliessman, 1998; Altieri and Anderson, 1986):

- a. They combine high species numbers and structural diversity in time and space (through both vertical and horizontal organization of crops).
- b. They exploit the full range of microenvironments (which differ in soil, water, temperature, altitude, slope, fertility, etc.) within a field or region.
- c. They maintain closed cycles of materials and wastes through effective recycling practices.
- d. They rely on the complexity of biological interdependencies, resulting in some degree of biological pest suppression.
- e. They rely on local resources plus human and animal energy, thereby using low levels of technology input.
- f. They rely on local varieties of crops and incorporate the use of wild plants and animals. Production is usually for local consumption. The level of income is low; thus the influence of noneconomic factors on decision making is substantial.

The Experimental Nature of Traditional Knowledge

The strength of traditional people's knowledge is that it is based not only on acute observation but also on trial and error and experimental learning. The experimental approach is very apparent in the selection of seed varieties for specific environments, but it is also implicit in the testing of new cultivation methods to overcome particular biological or socioeconomic constraints. In fact, Chambers (1983) argued that farmers often achieve a richness of observation and a fineness of discrimination that would be accessible to Western scientists only through long and detailed measurement and computation.

Yet only recently has some of this traditional knowledge been described and documented by researchers. The evidence suggests that the finest discrimination develops in communities where the environments have great physical and biological diversity and/or in communities living near the margins of survival (Chambers, 1983). Also, older community members possess greater, more detailed knowledge than younger members (Klee, 1980).

The Ecological Services of Biodiversity in Traditional Agroecosystems

In traditional agroecosystems, complex and diversified cropping systems are vital because the interactions among crops, animals, insects, and trees result in beneficial synergisms that optimize soil fertility, pest control, and productivity (Altieri, 1995; Harwood, 1979; Richards, 1985). Among the ecological services are the following:

1. By interplanting, farmers take advantage of the capacity of cropping systems to reuse their own stored nutrients. The tendency of some crops to deplete the soil is counteracted by interplanting other crops that enrich the soil with organic matter. Soil nitrogen, for example, can be increased by incorporating legumes in the crop mixture, and phosphorus assimilation can be enhanced by growing crops with mycorrhizal associations.
2. The complex structure of traditional agroecosystems minimizes crop loss to insect pests through a variety of biological mechanisms. The intercropping of diverse plant species provides habitats for the natural enemies of insect pests as well as alternative host plants for pests. For example, a crop may be planted as a diversionary host to protect other more susceptible or more economically valuable crops from serious damage. The diversity of crops grown simultaneously in polycultures helps prevent the buildup of pests on the comparatively isolated plants of each species. Where shifting cultivation is practiced, the clearing of small plots from secondary forest vegetation also permits the easy migration of natural pest predators from the surrounding forest.
3. Increasing the species and/or genetic diversity of cropping systems is a key strategy to minimize losses from plant diseases and nematodes (types of round-worms that are among the most widespread and damaging of agricultural pests). The mixing of different crop species or varieties can

delay the onset of diseases, reduce the spread of disease-carrying spores, and modify environmental conditions such as humidity, light, temperature, and air movement so that they are less favorable to the spread of certain diseases.

4. Many intercropping systems prevent competition from weeds, chiefly because the large leaf areas of their complex canopies prevent sufficient sunlight from reaching sensitive weed species. In general, the extent to which weeds present a problem depends on the type of crops and the proportion of the different species grown, their density, where they are planted, the fertility of the soil, and management practices. Weed suppression can be enhanced in intercrop systems by adding crop species that inhibit weed germination or growth. Crops such as rye, barley, wheat, tobacco, and oats release toxic substances into the environment, either through their roots or from decaying plant material. Such toxins inhibit the germination and growth of some weed species such as wild mustard (*Brassica* spp.) and poppy.
5. The integration of animals (e.g., cattle, swine, poultry) into farming systems, in addition to using them for milk, meat, and draft needs, adds another trophic level to the system, making it even more complex. Animals are fed crop residues and weeds with little negative impact on crop productivity, and this serves to turn otherwise unusable biomass into animal protein. Animals also recycle the nutrient content of plants by transforming them into manure. Furthermore, the need for animal feed broadens the crop base to include plant species that are useful for conserving soil and water (Reijntjes *et al.*, 1982). Legumes are often planted to provide quality forage, but they also improve the nitrogen content of soils. Integrated crop–livestock systems usually take the form of a crop–pasture rotation in which the pasture phase “charges” the system with nutrients and organic matter and the cropping phase “extracts” the accumulated nutrients. This balances biomass and nutrient inputs and outputs.

Preserving the Biodiversity of Traditional Agroecosystems

As many rural societies undergo the conversion from a subsistence economy to a cash agricultural economy, the loss of biodiversity in their ecosystems is mounting at an alarming rate. Because many peasants are directly linked to the market economy, external economic forces are increasingly influencing production by favoring genetically uniform crops and mechanized and/or agrochemical practices. Many landraces and wild plant relatives are being abandoned, which may cause them to become relic populations or even extinct. In some areas, land scarcity (mostly a result of uneven land distribution) has forced changes in land use and agricultural practices, which in turn have caused the disappearance of habitats that formerly maintained useful noncrop vegetation, including wild progenitors and weedy forms of crops (Altieri *et al.*, 1987).

In many parts of the world, genetic erosion is occurring at a fast pace because farmers are having to quickly change their

farming systems because of economic, technical, and social pressures. As farmers adopt high-yield modern varieties (HYVs), they often subdivide their farming systems into commercial (mostly devoted to HYVs) and subsistence sectors, growing native varieties in the latter. The greatest loss of traditional plant varieties is occurring in lowland valleys close to urban centers and markets (Brush, 1986).

Given these destructive trends, many scientists and development workers have emphasized the need for *in situ* conservation of native crop genetic resources and the environments in which they occur (Prescott-Allen and Prescott-Allen, 1981). However, most researchers believe that *in situ* preservation of landraces would require a return to or the preservation of microcosms of traditional agricultural systems, which some regard as an unacceptable and impracticable proposition (Frankel and Soulé, 1981). Nevertheless, the maintenance of traditional agroecosystems may be the only sensible strategy to preserve *in situ* repositories of crop germplasm. Although most traditional agroecosystems are undergoing some process of modernization or drastic modification, the conservation of crop genetic resources can still be integrated into agricultural development, especially in regions where rural development projects preserve the vegetation diversity of traditional agroecosystems and are anchored in the peasant rationale to utilize local resources and their intimate knowledge of the environment (Alcorn, 1984; Nabhan, 1983).

Previous recommendations for *in situ* conservation of crop germplasm emphasized the development of a system of village-level landrace custodians (a farmer curator system) whose purpose would be to continue growing a limited sample of endangered landraces native to the region (Mooney, 1983). One suggestion for preserving crop-plant diversity was for governments to set aside carefully chosen 5-by-20-km strips of land at as few as 100 sites around the world where native agriculture is still practiced (Wilkes and Wilkes, 1972). But given the increasing impoverishment and lack of income-generating alternatives for many rural populations in less developed countries, a proposition of this kind is clearly unrealistic since it fails to address the subsistence needs of these populations. In many areas where the urgent short-term goal of the local people is survival, diverting the limited land available for conservation purposes per se might prove totally inappropriate. A more feasible approach would be to support sustainable farming systems that incorporate native crops and wild/weedy relatives within and around production fields, as well as appropriate technologies aimed at upgrading food production for self-sufficiency (Altieri and Merrick, 1987). Such efforts would ensure that germplasm preservation remains linked to the economic and agricultural viability of local populations.

If biodiversity conservation is to succeed among small farmers, conservation goals and rural development efforts must be integrated to give equal importance to local resource conservation, food self-sufficiency, and equitable market participation. Any attempt at *in situ* crop genetic conservation must struggle to preserve the agroecosystem in which these resources occur (Nabhan, 1983). In the same vein, preservation of traditional agroecosystems cannot be achieved unless the sociocultural stability of the local community is also assured (Altieri, 1995).

An examination of effective grassroots rural development programs in less developed countries suggests that the process of agricultural improvement must (a) utilize and promote autochthonous knowledge and resource-efficient technologies, (b) emphasize use of local and indigenous resources, including valuable crop germplasm as well as essentials like firewood resources and medicinal plants, and (c) remain a self-contained, village-based effort with the active participation of the local people (Altieri, 1987). The subsidizing of a peasant agricultural system with external resources (e.g., pesticides, fertilizers, and irrigation water) can bring high levels of productivity, but such a system would then be sustainable only at high external cost and would depend on the uninterrupted availability of commercial inputs. In contrast, an agricultural strategy based on a diversity of plants and cropping systems can bring moderate to high levels of productivity through the manipulation and exploitation of the resources internal to the farm and can be sustainable at a much lower cost and for a longer period of time (Gliessman, 1998).

Using Biodiversity-Based Strategies to Support Traditional Agriculture

By understanding the common features of traditional agriculture, such as the capacity to bear risk, the use of biological folk taxonomies, and the production efficiencies derived from multiple and symbiotic crop mixtures, agricultural scientists have been able to develop technologies that support the needs and circumstances of specific groups. While subsistence farming generally lacks the potential for producing a meaningful marketable surplus, it does ensure food security. Many scientists wrongly believe that traditional systems do not produce more because hand tools and draft animals put a ceiling on productivity. However, where productivity is low, the cause appears to be social, not technical. When the subsistence farmer succeeds in providing food, there is no pressure to innovate or to enhance yields. Yet research shows that increased productivity is possible when traditional crop and animal combinations are adjusted and when labor and local resources are used more efficiently (Pretty, 1995).

As the inability of the Green Revolution to improve production and farm incomes for the very poor became apparent, growing enthusiasm for established, traditional agricultural practices generated a renewed quest in the developing world for affordable, productive, and ecologically sound technologies that could enhance small farm productivity while conserving resources. In the Andean altiplano, development workers and farmers have reconstructed a 3000-year-old indigenous farming system at an altitude of almost 4000 m. These indigenous farmers were able to produce food in the face of floods, droughts, and severe frosts by growing crops such as potatoes, quinoa, oca, and amaranthus in raised fields or "waru-warus," which consisted of platforms of soil surrounded by ditches filled with water (Browder, 1989).

Technicians have now assisted local farmers in reconstructing 10 ha of these ancient farms, with encouraging results, which later led to a substantial expansion of the area under warus. For instance, yields of potatoes from waru-warus

can surpass yields from chemically fertilized fields. Recent measurements indicate that waru-warus produce 10 tons of potatoes per hectare compared to the regional average of 1–4 tons/ha.

This combination of raised beds and canals has proven to have remarkably sophisticated environmental effects. During droughts, moisture from the canals slowly ascends the crop roots by capillary action, and during floods, furrows drain away excess runoff. Waruwarus also reduce the impact of temperature extremes. Water in the canal absorbs the sun's heat by day and radiates it back by night, thereby helping protect crops from frost. On the raised beds, nighttime temperatures may be several degrees higher than in the surrounding area. The system also maintains its own soil fertility. In the canals, silt, sediment, algae, and organic residues decay into a nutrient-rich muck that can be dug out seasonally and added to the raised beds. There is no need for modern tools or fertilizers, and the main expense is manual labor to dig canals and build up the platforms. This ancient technology is proving so productive and inexpensive that it is now being actively promoted throughout the Andean altiplano.

One of the early projects advocating the reconstruction of traditional farming systems occurred in Mexico in the mid-1970s when the then existing Instituto Nacional de Investigaciones sobre los Recursos Bioticos (INIREB) unveiled a plan to build "chinampas" in the swampy region of Veracruz and Tabasco. Chinampa agriculture was perfected by the Aztec inhabitants of the Valley of Mexico prior to the Spanish Conquest. It involves the construction of raised farming beds in shallow lakes or marshes, and represents a self-sustaining system that has operated for centuries as one of the most intensive and productive ever devised by humans. Until the last several decades, chinampas demanded no significant capital inputs yet maintained extraordinarily high yields year after year. A wide variety of staple crops, vegetables, and flowers are often mixed with an array of fruit trees and bushes. Abundant aquatic life in the canals provides valuable sources of protein for local diets (Gliessman, 1998).

Now threatened by the sprawling growth of Mexico City and its suburbs, chinampas have nearly vanished except in a few isolated areas. Regardless, this system still offers a promising model as it promotes biological diversity, thrives without chemical inputs, and sustains year-round yields. When INIREB first began to establish the chinampa system in the lowland tropics of Tabasco, implementation and adoption met with mixed success. Some critics felt that no market outlets were explored or developed for the new outputs produced by the community. Nevertheless, the "raised beds" of Tabasco (or *camellones chontales*) are still in full operation in the swamps of this region, and apparently the local Chontal Indians have full control of them. The Chontal practice traditional agriculture, and these raised beds produce a great variety of products, which in turn have enhanced the income and food security of these "swamp farmers."

In a completely different ecoregion in the Andes, several institutions have engaged in programs to restore abandoned farming terraces and build new ones. In the Colca Valley of southern Peru, PRAVITIR (Programa de Acondicionamiento Territorial y Vivienda Rural) sponsors terrace reconstruction by offering peasant communities low-interest loans, seeds, and

other inputs to restore large areas of abandoned terraces. The main advantages of using terraces are that they minimize risks in times of frost or drought, reduce soil loss, amplify the cropping options because of microclimate and hydraulic differences, and thus improve crop yields. Yield data from new bench terraces showed a 43–65 percent yield increase in potatoes, maize, and barley compared to yields of these crops grown on sloping fields. One of the main constraints of this technology is its high labor intensity, requiring about 350–500 worker-days per hectare for the initial building of the terraces. Such demands, however, can be buffered when communities organize and share tasks (Browder, 1989).

Another example of how a biodiversity-based approach can support or even resurrect traditional agriculture is occurring on Chiloé Island in southern Chile. This is a secondary center of origin of potatoes, and development workers are currently tapping the ethnobotanical knowledge of elderly female Huilliche Indians in an effort to slow genetic erosion and to recover some of the original native potato germplasm. They intend to provide impoverished farmers with locally adapted varieties that can produce without the use of agrochemical fertilizers. After surveying several agroecosystems on Chiloé, technicians collected hundreds of samples of native potatoes still grown by local farmers, and with this material, and in collaboration with farmers, they established community seed banks where more than 120 traditional varieties are grown year after year and are subjected to selection and seed enhancement. In this way, an *in situ* conservation program has been initiated involving farmers from various rural communities, thus ensuring the active exchange of varieties among participating farmers. As more farmers become involved, this strategy will provide a continuous supply of seeds to resource-poor farmers and will also create a repository of vital genetic diversity for future regional crop improvement programs (Altieri, 1995).

Conclusions

A key conclusion that emerges from the relevant anthropological and ecological literature is that, when not disrupted by economic or political forces, indigenous modes of food production generally preserve rather than destroy biodiversity and natural resources. In fact, in any particular region, capitalist development through the promotion of large-scale, energy-intensive, commercial agriculture is bound to deplete natural resources more than some of the existing traditional systems. A number of studies have proven that many traditional agricultural systems are highly sustainable and productive, offering an alternative to the capital-intensive agriculture currently promoted by many development and governmental agencies. Besides employing crop diversity, traditional farmers use a set of practices that often cause minimal land degradation. These include the use of terraces and hedgerows in sloping areas, minimal tillage, mulching, small field sizes, and long fallow cycles (Grigg, 1974; Brush, 1982; Richards, 1985; Netting, 1993). It is clear that this more traditional strategy is both ecologically informed and environmentally sound, as the agricultural practices that are most likely to endure are those that deviate least from the native diversity of the natural

plant communities within which they exist (Altieri, 1995; Gliessman, 1998).

This assessment of traditional subsistence agriculture does not romanticize its origins or practitioners, nor does it consider development per se to be detrimental. The intention is rather to stress the demonstrated value of traditional agriculture in the preservation of biodiversity, native crop diversity, and the adjacent vegetation communities (Toledo, 1980). Basing a rural development strategy on traditional farming and ethnobotanical knowledge not only assures the continual use and maintenance of valuable genetic resources, but also allows for the diversification of peasant or other indigenous subsistence strategies (Alcorn, 1984; Caballero and Mapes, 1985), which is a crucial issue in times of economic uncertainty.

The study of traditional agroecosystems and the ways in which indigenous peoples maintain and use biodiversity can facilitate the discovery of valuable agroecological principles, which in turn can contribute to the development of more sustainable agroecosystems and biodiversity conservation strategies in both developed and less developed countries.

Glossary

Agricultural intensification Process by which farming systems increasingly use high levels of nonrenewable, purchased inputs, e.g., inorganic fertilizers and other agrochemicals for pest suppression, substitute mechanization, and fossil fuels for human labor and increase capital invested per unit of land.

Agrobiodiversity The variety and variability of living organisms that contribute to food and agriculture in the broadest sense, and that are associated with cultivating crops and rearing animals within ecological complexes.

Conservation agriculture Farming practices that maintain a permanent or semipermanent organic soil cover, as a growing crop or a dead mulch to protect the soil physically and to feed soil biota, which improves soil quality.

Ecoagriculture Land use approaches that achieve agricultural production and sustain rural livelihoods in ways that also protect wild plant and animal species and the natural ecosystem services upon which both humans and wildlife depend.

Ecosystem approach Strategy for the integrated management of land, water, and living resources that promotes conservation and sustainable use in an equitable way.

Ecosystem services Ecological functions and processes by which the environment provides for human needs, e.g., clean water, timber, habitat for fisheries, pollination, and esthetic values.

Insurance hypothesis Biodiversity insures that ecosystems maintain functions because more species guarantee that some will continue to function even if others fail, thereby enhancing the capacity to recover from, and mitigate the risks caused by disturbance.

Land sparing On-farm management practices to increase yields per unit land area with the goal of minimizing the pressure to convert land in natural ecosystems for agriculture, so that wildlife in natural ecosystems persists, but at the potential cost of decreasing wildlife populations in and around intensified farmland.

Market-based instrument Policy mechanism in which a change in technology, behavior, or the mix of inputs and outputs is encouraged through financial incentives, such as subsidies, taxes, or market creation; its use is intended to align the social and private values of agrobiodiversity.

Market failure The lack of appropriate markets or the incapacity of existing markets to reflect the social value of agrobiodiversity through prices.

Niche complementarity Differential acquisition and use of resources by different species; niches of different species differ which results in more complete utilization of resources in spatially or temporally complex environments.

Organic agriculture Farming practices that rely on biological inputs and diversity for soil fertility and pest and disease suppression; organic farms that are certified by government policies or private organizations are not allowed to use synthetic pesticides or fertilizers.

Planned versus unplanned biodiversity Crops and livestock that are purposefully introduced and maintained in an agroecosystem (planned biodiversity) versus associated biodiversity that includes all soil biota, herbivores, carnivores, decomposers, and any other species that exist in or colonize the agroecosystem (unplanned biodiversity).

Resilience Capability of a system to adapt to external changes by either returning to its original state or evolving into a state preferable to the initial one; persistence, adaptiveness, variability, and unpredictability are all attributes that contribute to resilience.

Social benefits of conservation Array of benefits enjoyed by society from the conservation of agrobiodiversity that need not coincide with the values reflected by food and fiber markets which often accrue to the individual users of agrobiodiversity such as farmers; the wedge between private and social value reflects the external value of agrobiodiversity.

Use-value of agrobiodiversity Benefits accrued to users of agrobiodiversity directly by enhancing agricultural productivity, including increases in yields and savings in artificial inputs, and indirectly by enhancing stability and resilience of the agricultural system; nonuse values include the “option” value that arises from the future potential benefits of agrobiodiversity not necessarily known in the present, and the “existence value” stemming from human ethical considerations relating to matters such as the extinction of species and ecosystem.

Wildlife-friendly farming On-farm management practices as benign to wildlife as possible at the potential cost of decreasing yields; reduction in pesticides and fertilizers and their effects on nontarget organisms, and retention of patches of nonfarmed habitats and less-intensively farmed seminatural habitats within the agricultural landscape.

Introduction

Agrobiodiversity has always formed the basis for human food production systems, and has provided cultural, spiritual, religious, and esthetic value for human societies (Brush, 2004). Planned agrobiodiversity is the biodiversity of the crops and livestock chosen by the farmer (Figure 1), while unplanned biodiversity refers to the associated biota, for example, soil microbes and fauna, weeds, herbivores, and carnivores, colonizing the agroecosystem and surviving according to the local management and environment (Vandermeer and Perfecto, 1995). Rapid loss of agrobiodiversity is now occurring worldwide, as an indirect result of population growth in the developing world and the high per capita consumption of natural resources in the industrialized world, affecting the production of food, fuel, and fiber and also many ecological services such as those supporting water supplies, health, and wildlife habitat. Most (75%) of the world's poor people live in rural landscapes, and will be especially vulnerable to these changes (WRI, 2005).

A wide range of disciplinary sciences has contributed to understanding the functions of agrobiodiversity, as illustrated by the following examples. The agricultural sciences have shown that crop and animal breeding can select for genes to increase agricultural productivity (e.g., Cooper

et al., 2001). Crop diversity, in both space and time, can enhance nutrient use efficiency, and a diverse soil community may regulate tighter nutrient cycling, reduce pests and diseases, and improve soil structure (e.g., Brussaard *et al.*, 2007). Ecological research has shown that biodiversity can increase the stability of grassland ecosystems (Loreau *et al.*, 2002), which has implications for the management of pastures for livestock production. Additionally, the structure of agricultural landscapes, that is, mosaics of agricultural and nonagricultural ecosystems, is increasingly recognized as an important factor for the utilization and conservation of both on- and off-farm biodiversity. Economics has shown that by investing in biodiversity, environmental and market risks faced by producers can potentially be reduced, especially over the long term (Perrings, 1998). Interdisciplinary approaches in which the agroecological value of biodiversity is combined with the socioeconomic value, especially those focused on how managing biodiversity can be enhanced in agricultural practices, are now viewed as an important new direction of agrobiodiversity research (Jackson *et al.*, 2005). Although the agrobiodiversity literature focuses mainly on farming systems, many of the issues and approaches are also relevant to food, fiber, and timber production in natural ecosystems such as grazed grasslands, managed forests, and fisheries.

Figure 1 Planned and unplanned (or associated) biodiversity in selected farming systems. Both types of biodiversity support ecosystem services such as nutrient cycling, pest control, and pollination. Low values of associated biodiversity within cultivated fields are indicative of intensive farming systems, and thus are present in several of the types of farming systems. Cereal production, as an example, occurs in many permutations worldwide, and a wide range of associated biodiversity is possible. The same pattern probably characterizes livestock husbandry. Reproduced with permission from Figure 26.4, p. 758, in Cassman KG and Wood S (2005) Cultivated systems. In: Hassan R, Scholes R, and Ash N (eds.) *Ecosystems and Human Well-Being Current State and Trends*, Ch 26. Washington, DC: Island Press.

This is because the adoption of biodiversity-based practices for agriculture is not solely based on functions and services that society as a whole obtains from such functions. It is individual farmers who are ultimately the agents who decide how much natural capital to conserve and utilize, and will do that based on their own objectives and needs, and the social, economic (e.g., markets and policies), and environmental conditions in which they operate. The multiple interactions between farmers and the natural resources they use, and between farmers and the institutional environment, create different farming practices and styles, which result in local specificity and regional heterogeneity of the natural and social environments which may either enhance or reduce agrobiodiversity. The private and social values of biodiversity often differ widely (Figure 2). Individual farmers tend to react to the private use-value of biodiversity when reflected in the marketplace and thus typically ignore the “external” benefits of conservation that accrue to the wider society. This currently implies an overexploitation of biodiversity, thus imposing excessive costs on society at large. Institutional intervention through incentives is therefore needed to ensure that agrobiodiversity will be used and conserved to its full potential of functional benefits.

Fortunately, awareness of the need for sustainable agricultural production has increased, in response to the unprecedented population growth, food demand, and regionally high per capita use of natural resources and global environmental change that is now occurring. The focus is shifting to a greater reliance on ecological goods and services, which is especially important for modern intensive agriculture, since there will be less-damaging effects on environmental quality and on the biodiversity of wildlands. Conservation of existing biodiversity in agricultural landscapes and the adoption of biodiversity-based practices have been proposed as ways to increase the sustainability of agricultural production (Collins

and Qualset, 1999; McNeely and Scherr, 2003). For example, in the Millennium Ecosystem Assessment (MEA, 2005), biodiversity is viewed as an important coping strategy against agricultural risks in an uncertain future. A successful transition to a biodiversity-based paradigm for agriculture requires fundamental knowledge and understanding of biodiversity as natural capital for providing ecosystem goods and services for agriculture, the direct and indirect use-value in economic terms that are derived from these goods and services, and the social forces, including poverty, that will promote or impede its sustained adoption (Swift *et al.*, 2004; Wood and Lenné, 2005).

Agrobiodiversity and Modern Agricultural Intensification

Rapid Land-Use Change to Meet World Food Demand

Modern intensive cropping systems have greatly increased the global food supply by utilizing high-yielding genotypes that demand high levels of synthetic inputs (e.g., inorganic fertilizers and other agrochemicals for pest suppression, irrigation, and fossil fuels) (Matson *et al.*, 1997; Evenson and Gollen, 2003). However, there have been significant environmental costs in terms of increased pollution, loss of biodiversity in both agroecosystems and in wildlands, and loss of traditional knowledge associated with biodiversity. Furthermore, economic subsidies paid to modern intensive agriculture have also led to the oversupply, from ecological and economic points of view, of crops and associated agrichemicals (MEA, 2005).

The world's population of 6.3 billion people is projected to grow to 9 billion by 2050. At present, 10% of the global land area is under modern, intensive agricultural use, 17% is under

Figure 2 Linkages between social and individual or private values of biodiversity conservation. When the social value outweighs the individual value, then biodiversity is underprovided by the direct land users. Policies are needed to correct such market failure.

Figure 3 Marked declines in bird species populations across the United Kingdom are due to agricultural intensification (Donald *et al.*, 2001), especially many upland grassland bird species (Henderson *et al.*, 2004). The index is the percentage change in bird species in various categories relevant to a 100% baseline value for 1970. Reproduced from DEFRA (2004) Indicators of Sustainable Development. Sustainable Development Unit, Department of Environment, Food, and Rural Affairs, UK, <http://www.defra.gov.uk/corporate/sdstrategy/chapter3.htm> (accessed November 2006).

extensive use associated with a lower application of artificial inputs, and 40% is grazed by domestic livestock (Wood *et al.*, 2000; Mooney *et al.*, 2005). It is projected that by 2050, food production must double to meet human needs and hence it is expected that more land will be converted into agriculture. Further intensification on already converted land is also expected to increase through greater reliance on synthetic, off-farm inputs unless more sustainable paradigms are developed (Clay, 2004).

Irrigated and pasture lands are both expected to double in area by 2050, with a net loss of 10^9 ha of wildlands worldwide, thereby increasing the global pressure on biodiversity in natural ecosystems. Agricultural intensification not only leads to a loss of diversity of breeds and associated agroecosystem biodiversity, such as farm birds (Figure 3), beneficial insects, and soil biota, but it can also put wild biodiversity at risk through gene flow from domesticated varieties to wild species, exposure to potentially virulent pathogens *via* cross-species transmission, and adverse effects of agrochemicals on nontarget species in adjacent wildland ecosystems. It is possible that a wide range of ecosystem services are thereby affected, including but not limited to provisioning services that support production of food, fuel, and fiber; regulating services such as pollination and pest control; and supporting services such as nutrient cycling and water purification.

Several of the projected long-term human population growth trends are likely to impact agrobiodiversity through land-use changes in agricultural landscapes (Kates and Parris, 2003). Cities will expand to accommodate the growing urban population, and rural populations will proportionately decrease. In turn, agroindustrialization will increase in many regions, resulting in increased processing of food, use of off-farm sources of inputs, distribution of globalized farm technologies, and vertical coordination, in which management units at different stages of production and processing are owned by the same firm, and product flows are coordinated through administrative means (Reardon and Timmer, 2005). Large agribusiness firms may increasingly dominate food

production systems, with concomitant increases in large-scale farming and marketing operations, which may jeopardize the livelihoods of small farmers. In contrast, stabilization of agricultural livelihoods of rural populations in many low-income countries may occur if higher energy prices for transport and lower communication costs provide incentives for less-concentrated patterns of settlement, and greater reliance on local agricultural products.

Besides population dynamics, global impacts of climate change are also expected to alter agricultural landscapes. Developing regions, and Africa in particular, are most vulnerable to the impacts of projected changes because existing widespread poverty limits adaptation capabilities. Figure 4 shows the predicted transition between pastoral and mixed agro-pastoral systems in Africa. The land-use change projections indicate that for Africa, there will be a decrease in the total area in which cropping will be possible by 2050 (Thornton *et al.*, 2002). Coupled with population growth, and the decline of large tracks of arable land, further agricultural intensification is very likely.

Agrobiodiversity and Sustainable Agriculture

The broad concept of “sustainable agriculture” is characterized by a set of complementary goals: producing more food and fiber, protecting the resource base upon which agriculture depends, and promoting social well-being. A widely accepted definition of sustainable agriculture in the United States is one that “will over the long term”¹

- satisfy human food and fiber needs
- enhance environmental quality and the natural resource base upon which the agricultural economy depends
- make the most efficient use of nonrenewable resources and on-farm resources and integrate, where appropriate, natural biological cycles and controls

¹1990 Farm Bill (US Government 1990).

Reproduced from Thornton PK, Kruska RL, Henninger N, *et al.* (2002) *Mapping Poverty and Livestock in the Developing World*, 124pp. Nairobi, Kenya: ILRI (International Livestock Research Institute).

- sustain the economic viability of farm operations
- enhance the quality of life for farmers and society as a whole.”

The utilization of agrobiodiversity provides a set of tools and approaches to intensify agricultural production and still support sustainable agriculture (Srivastava *et al.*, 1996).

Agriculture is both a threat to biodiversity and a key to its survival. Unless agriculture is sustainably intensified, many remaining wild areas will succumb to the plow, ax, or herds of grazing livestock. With global demand for food and other agricultural products expected to at least double – and perhaps even triple – over the next 50 years, the productivity of existing farms and rangelands will have to increase dramatically. How this intensification process plays out in the decades ahead will largely determine how many species – and their habitats – will survive into the coming century.

Traditional agriculture is regarded as more sustainable than intensified agriculture, due to strategies that minimize risk and stabilize yields, promote diversity in diets, and utilize practices that require low levels of technology and efficient use of limited inputs (Altieri, 2004). At present, most of the world’s population lives in rural areas and depends to some extent on traditional agricultural systems (Brookfield *et al.*, 2003). But as the pressure for more food increases, innovative biodiversity-based solutions are needed to support sustainable agriculture relevant to specific locations and farming systems. Some will build upon traditional practices, such as replanting of clonal

rubber trees within agroforests to avoid low-income regrowth phases in Sumatra (Joshi *et al.*, 2003), or utilizing species-rich Mediterranean grasslands that have higher water-use efficiency than monocultures to increase water-use efficiency compared with monoculture (Caldeira *et al.*, 2001). Others may be based on production systems that mimic natural systems, for example, domestication of stress-tolerant native perennial grasses such as grain crops, as promoted by the Land Institute (Salina, Kansas). But the main source of biodiversity-based innovation for sustainable agriculture is likely to come from ecosystem approaches that blend ecology, agronomic and horticultural technologies, and socioeconomic analysis to develop high-yielding and sustainable farming systems. Current examples that have been shown in some cases to achieve these objectives are conservation agriculture, which uses farming practices that maintain a permanent or semipermanent organic soil cover to increase soil quality and reduce fuel use; and organic agriculture, which relies on biological inputs and diversity for pest management and soil fertility.

Agrobiodiversity and Resilience to Environmental Change

The capability of a system to adapt to external changes by either returning to its original state or by evolving into a state preferable to the initial one is referred to as resilience. Resilience also involves a quantitative/dynamic aspect in terms of the rate with which the system returns to equilibrium, for

example, highly diverse soil communities were more resistant to an imposed stress than low-diversity communities (Griffiths *et al.*, 2000). A basic hypothesis, shared by ecologists and economists, is that various functions of biodiversity contribute to the resilience of agroecosystems. For example, increasing the diversity of annual crops and trees in agroecosystems can improve the spatial and temporal efficiency of resource use as well as the economic viability for farmers by diversifying their revenues under uncertain market conditions with respect to volatile market price changes of inputs, crops, or tree products.

Biodiversity is thought to enhance the capacity to recover from disruption of functions, and the mitigation of risks caused by disturbance. This may be most important at larger spatial and temporal scales, by providing insurance value, especially when dispersal abilities of organisms allow for immigration within the landscape (Loreau *et al.*, 2003, Figure 5). The insurance hypothesis proposes that species or phenotypes that appear to be functionally redundant for a specific ecosystem process at a given time and space may actually diverge in response to a new set of environmental conditions. Redundancy is strongly dependent on the type of agroecological functions. For example, “narrow” processes such as soil nitrification are associated with low redundancy, while broad processes such as soil organic matter decomposition or N-mineralization are carried out by a large variety of species, hence redundancy is high.

At the larger landscape scale, ecosystem functions would be expected to be more stable and less subject to fluctuation in species-rich landscapes. Heterogeneous composition of ecosystems in agricultural landscapes may thus provide insurance value that is not detected by the local-scale experiments that are typical of most agricultural research. More diversity in crops, management strategies, and mosaics of ecosystems in the landscapes may ultimately be socially desirable. On the short term, less agrobiodiversity would make the system more stable in the sense that there is less variation in producer or

consumer behavior following minor perturbations. But on the long term, it may also reduce the capacity of that system to absorb greater environmental or economic risks. The uncertainties associated with rising CO₂ concentrations and temperature suggest that agricultural responses to global climate change may benefit from the resilience that results from increasing agrobiodiversity at the landscape level.

Strategies to Protect Wildlife in Agricultural Landscapes

There has been much debate over cropland expansion versus intensification in agricultural landscapes to increase food supply and enhance environmental services and biodiversity of wild species (Donald, 2004; Green *et al.*, 2005; Mooney *et al.*, 2005). Usually, two scenarios are considered: (1) wildlife-friendly farming would use lower agrichemical inputs to reduce impact on nontarget biota, but would expand production of less-intensive, often low-yielding cultivation systems into wildlands to meet food demands or (2) land sparing by intensifying agriculture using agrichemical inputs and monocultures to produce more food per unit land area would result in less increase in the area of cultivated lands at the potential cost of decreasing wildlife populations in and around farmland, but would save wildland biodiversity. These extremes are too simplistic. For one reason, high-input, modern agriculture can quickly expand to dominate an agricultural landscape, as the efficiency of production often increases with the volume of goods, that is, economy of scale, so that land sparing does not materialize. Another reason is that biodiversity-friendly agriculture can offer sustainable alternatives that maintain or increase agriculture productivity with positive benefits for wildlife, for example, ecoagriculture (McNeely and Scherr, 2003), so that both wildlife-friendly farming and land sparing are achieved.

Forest–agricultural ecotones are the areas that adjoin forests and other natural habitats and that lie between forests and zones of intensive agriculture. They often support both high biodiversity and human populations (Rosenzweig, 2003). Conservation can be enhanced if there is less-direct dependence on forests in the form of collection of nontimber forest products, and instead, greater choices for livelihoods derived from diversification of farming systems and use of nonforest products. Nongovernmental organizations, such as ATREE and Ecoagriculture Partners, have effectively demonstrated that imparting ideas for simple technologies can increase yields, profitability, and diversification of livelihoods, thereby reducing the impact on the biodiversity within the forest zone (McNeely and Scherr, 2003; Bawa *et al.*, 2007).

When native vegetation is cleared for agriculture, habitats which were once continuous become divided into separate fragments, which become islands isolated from each other by cropland, pasture, and urban areas. These islands are not favorable for the set of species which require interior habitat, and cannot survive in the habitat along edges of fragments, which experience a different microenvironment. One solution is to plant corridors of native vegetation to link fragments; another is to increase the amount of interior habitat. Landscape planning to reduce habitat loss and fragmentation has focused on population persistence, mainly of birds and

Figure 5 The biological legacy or ecological memory present in or near a disturbed area affects the reestablishment and organization of biota. Future community composition depends on spatial configuration of habitats and distance to source areas. Severe uniform disturbances result in loss of many species (left). Colonization and reorganization require that disturbed areas are in close proximity to undisturbed patches (right). Reproduced from Bengtsson J (2002) Disturbance and resilience in soil animal communities. *European Journal of Soil Biology* 38: 119–125.

mammals, with respect to species' sensitivity to isolation and area effects. The effect of the characteristics of the matrix of ecosystems in the landscape is gradually gaining more attention (Swihart and Moore, 2004).

Ecological Functions of Agrobiodiversity

Agrobiodiversity is most likely to enhance ecosystem functioning when a unique or complementary effect is added to an ecosystem, for example, by planting genotypes with specific genes for higher yield or pest resistance, mixing specific genotypes of crops (Zhu *et al.*, 2000), using more crops in rotation, supporting more parasitoids or insect enemies with specific roles in controlling pests (Tscharntke *et al.*, 2005), or including a plant functional group, such as a legume, that increases nitrogen inputs and cycling (Drinkwater *et al.*, 1998). Current evidence suggests that merely adding more species to most agroecosystems has little effect on function, given the redundancy in many groups, especially for the soil biota (Swift *et al.*, 2004).

Agrobiodiversity: Genetic and Population Diversity

Genetic and population diversity has been successfully used in many ways for direct-use value for agricultural production. In modern production systems, the focus has been on identifying traits that increase yield, keeping up the treadmill of rapidly changing virulence of specific diseases, meeting the demand for resistance to an increased range of biotic and abiotic stresses, or increasing the temporal and spatial production of commodities that are destined for different uses or planted at different times of the year (Cassman *et al.*, 2003). Some of the gene pool available for crop improvement in the future has been safeguarded in gene banks for the major crops (Table 1).

In traditional production systems, farmers and communities opt to maintain a number of traditional varieties because they (1) meet their multiple needs more closely than modern ones, for example, grains that provide food for humans and forage for animals; (2) perform better under low levels of external inputs such as pesticides and herbicides; and

(3) are less sensitive to abiotic stress, due to ecophysiological traits or due to the use of genotypic mixtures that minimize risk in seasonal differences (Ceccarelli, 1996).

Historically, agricultural breeders used landraces and crop wild relatives to introduce improved pest resistance, yield, and quality genes into crops and livestock (Cooper *et al.*, 2001). In most cases, crop breeders have selected for morphological and developmental traits, rather than increased rates of photosynthesis or other physiological processes (Sinclair *et al.*, 2004). Breeding has been facilitated by understanding the genetic aspects of adaptation, and developing innovative breeding methods that are more environmentally and culturally acceptable than genetic engineering, such as marker-assisted selection (Gepts, 2002). Readily available genetic sequence information and genetic and physical maps open new possibilities for introgressing traits for stress tolerance and disease resistance (Engels *et al.*, 2002) and will further increase utilization of agrobiodiversity at the genetic and population levels.

Agrobiodiversity: Communities and Ecosystems

Increased plant species richness can have significant effects on ecosystem processes, based on mixtures of approximately 1–20 species in grasslands (Loreau *et al.*, 2002). This can be attributed to niche complementarity (i.e., differential resource used by different species), positive interactions between organisms, and greater resource capture than in species-poor communities (Tilman *et al.*, 2001). By inference, small increases in biodiversity may have a large effect on ecosystem functions such as productivity in agricultural communities composed of only a few species (de Wit, 1960), yet trophic interactions may make outcomes more complicated (Lewis *et al.*, 1997).

A good example of the benefits of using an ecosystem approach, rather than a reductionist approach that focuses on specific organismal interactions is the role of agrobiodiversity in pest-control strategies such as planting crop mixtures, integrating plants with natural defences against herbivore attack, for example, toxin biosynthesis, releasing natural enemies, and enhancing the complexity of the soil food web (van Bruggen and Termorshuizen, 2003). However, these must be integrated with management practices of the specific cropping system

Table 1 Percentage of gene pool remaining to be collected for major world crops, based on surveys of crop experts. The numbers lack precision due to the possibility of duplication and to incomplete knowledge of the gene pool of each crop

Crop	Estimated, mid-1980s percentage	Estimated 1986 percentage	Estimated, mid-1990s percentage
Wheat	10	5	5
Rice	8–15	30	5
Maize	2	10	5
Sorghum	25	20	20
Pearl millet	<30	20	
Potato	10–20	5	5
Sweet potato	>50	40	50
Cassava	25–33	65	
Soybean	30	40	
Common bean	<50	50	35

(Lewis *et al.*, 1997). Ideally, species assemblages will provide a set of multifunctions, but these raise issues about trade-offs (Gurr *et al.*, 2003). For example, weeds can favor natural enemies of insect pests by providing nonhost foods (e.g., pollen, nectar, alternative hosts, and prey) and shelter. Thus, weed-management practices, for example, herbicide application, must be evaluated in terms of a range of different biota and functions, which are unique to specific agroecosystems.

Changes in community structure often occur simultaneously with changes in inputs, making it hard to differentiate the effects of biodiversity. For example, long-term organic management can lead to higher biodiversity of plants, arthropods, and soil microbial functional groups and greater soil C sequestration, than long-term conventional management. However, the subsequent changes in ecosystem function cannot be simply attributed to higher biodiversity, because other inputs involved with organic production also vary substantially, for example, fertilizers, manures, and legume-based crop rotations (Mäder *et al.*, 2002).

Species interactions can be complicated, and are not always repeatable. As an example, a more complex rotation can alter crop nutritional properties but also increase attacks by insect pests. For soil biota, it is especially difficult to attribute ecosystem functions to biodiversity, since numerous species, many of which are unidentifiable, contribute to soil activity and aboveground responses (Swift *et al.*, 2004; Wardle *et al.*, 2004). Thus, idiosyncratic effects on soil biota can occur, even with the same plant species, or same plant community, or a similar soil type.

Based on these considerations, assessing species diversity and community assemblages for multifunctionality, along with gauging inputs to maximize economic benefit and environmental quality, is important for sustainable agriculture. This requires interdisciplinary research, an ecosystem approach, and often site-specific analyses across different types of gradients.

Agrobiodiversity: Landscapes

The insurance hypothesis of biodiversity, that is, that higher numbers of species increase resilience and reorganization after disturbance, may be most relevant at the landscape level (Loreau *et al.*, 2003; Swift *et al.*, 2004). Agricultural landscapes that are composed of a mosaic of well-connected early and late successional habitats may also be more likely to harbor biota that contribute to regulating and supporting services for agriculture, compared with simple landscapes (Bengtsson *et al.*, 2003). This idea, however, is not easy to demonstrate. As an example, European agrienvironmental schemes support direct payments to farmers to provide environmental benefits, but the observed species richness of birds and vascular plants increased slightly or not at all, whereas there were more consistent increases for arthropods (Kleijn and Sutherland, 2003). This may have been due to the low frequency of natural and seminatural areas in these agricultural landscapes, and thus, there were few opportunities for dispersal of species and functional groups of insects from relatively undisturbed habitats into agricultural production areas (Duelli and Obrist, 2003). But a more general

problem is finding truly paired replicates that constitute a robust research design.

Research on landscape-level biodiversity requires close association with farmers and other land managers, and involvement with stakeholders that care about the boundaries between agricultural and nonagricultural ecosystems. These human interactions are necessary for both the conservation of undisturbed natural ecosystems and traditional human land-use systems. Landscape-level biodiversity research poses some major issues related to scale. Agroforestry research in Southeast Asia has shown that a useful approach is to emphasize both local and regional data collection, and assess trade-offs between different types of services provided under landscape scenarios that vary in the following frequency and intensification both with direct data collection and with models (Murdیارso *et al.*, 2002; van Noordwijk, 2002).

The economic assessment of services provided by agrobiodiversity at the landscape level is contingent on the juxtaposition of different types of agricultural and nonagricultural ecosystems. Simple calculations have shown that pollination services contributed by wild bees increase yields and thus profitability on a farm field (Kremen *et al.*, 2002; Ricketts *et al.*, 2004). Even so, there are costs associated with leaving land out of agricultural production to protect the bees' nearby undisturbed habitats. Modeling approaches can show the trade-offs between various aspects of environmental quality, economics, and social welfare that change when biodiversity-based practices are adopted, especially when trade-offs are complex and depend strongly on scale (Hietala-Kiovu *et al.*, 2004; van Noordwijk, 2002).

Agrobiodiversity Utilization and Conservation: Socioeconomic Considerations

The economic value of the changes in agrobiodiversity and its associated services is rarely reflected in current market transactions. Therefore farmers, as the direct users of agrobiodiversity and usually decision-makers in general, do not pay sufficient attention to these services. This implies that there is too little incentive to maintain sufficient diversity to meet the needs of society in the context of multifunctional agricultural systems. The main problem is that markets for agricultural inputs and outputs do not reflect the full social opportunity costs. Economists refer to this as the problem of market failure, and to the resultant loss of biodiversity as an external effect of agricultural markets that creates excessive social costs. Many policies, particularly in agriculture, aggravate the problem by modifying agricultural prices in ways that increase the gap between the value of agrobiodiversity faced by private users (e.g., farmers) and the social value that better reflects the perceived scarcity of agrobiodiversity by society, for example, price supports for intensively managed crops. An alternative is rewards or payments for ecosystem services that result from adoption of biodiversity-friendly practices (Figure 6).

To resolve these problems, a different outlook on biodiversity in agricultural landscapes is needed (Perrings *et al.*, 2006). Biodiversity should be considered part of the natural capital that generates a flow of ecosystem services, upon which society depends, that is, interest on that capital. Just as private

Figure 6 Linkages between providers and beneficiaries of environmental services derived from dynamic biodiversity-rich landscapes, each supporting biodiversity utilization and conservation by different mechanisms. Reproduced from van Noordwijk M, Chandler FJ, and Tomich TP (2004) *An Introduction to the Conceptual Basis of RUPES: Rewarding Upland Poor for the Environmental Services They Provide*, 46pp. Bogor: ICRAF-Southeast Asia.

investors select a portfolio of produced capital to maintain the return on capital over a range of market risks, so must society choose the mix of genes, species, and ecosystems to maintain the flow of ecosystem services over a range of risks for environmental quality and human well-being, including poverty alleviation. Risks may arise from changes in that mix, and these risks must be understood and used to inform conservation strategy and policy.

New types of communication and cooperation are necessary for evaluating the potential for the utilization and conservation of biodiversity in agricultural landscape, for example, among agriculturalists, ecologists, and economists to identify and establish adequate assessment strategies (Robertson and Swinton, 2005), between anthropologists and ecologists to preserve ethnobiological species and functions (Brush, 2004), and between conservation biologists and agriculturalists to resolve priorities for managing genetic, species, and ecosystem diversity in agricultural landscapes (Banks, 2004). In addition, bridging between the natural and the social sciences will improve the success of engaging farmers and other stakeholders to use biodiversity-based solutions for increasing agricultural production in a sustainable manner (Pretty and Smith, 2004). These are themes promoted by the international program of biodiversity science, DIVERSITAS, which has identified a science agenda for agrobiodiversity in support of sustainable agriculture that promotes interdisciplinary communication, with the goal of inspiring and facilitating new research approaches for understanding the role of biodiversity in agricultural landscapes (Jackson et al., 2005).

Glossary

Aquaculture The farming of aquatic organisms, including fish, mollusks, crustaceans, and aquatic plants. Farming implies some sort of intervention in the rearing process to enhance production, such as regular stocking, feeding, or protection from predators. Farming also implies individual or corporate ownership of the stock being cultivated (Definition by FAO).

Broodstock Fish or shellfish from which a first or subsequent generation may be produced in captivity, whether for growing as aquaculture or for release to the wild for stock enhancement.

Ecosystem service Ecosystem services are the benefits people obtain from ecosystems. These include provisioning services such as food and water; regulating services such as flood and disease control; cultural services such as esthetic and recreational, values; and supporting services, such as nutrient cycling, which maintain the conditions for life on Earth.

Farming intensity In a broad continuum, extensive systems are those which are closest to natural fisheries, requiring minimal inputs and offering relatively low yields, whereas intensive systems require a large amount of inputs to maintain an artificial culture environment, with high yields. Between these extremes are the varying degrees of semi-intensive aquaculture, where definitions are less distinct: (i) extensive aquaculture does not involve feeding

of the organism, (ii) semi-intensive aquaculture involves supplementation of natural food by fertilization and/or the use of feeds, and (iii) intensive aquaculture is when the culture species is maintained entirely by feeding with nutritionally complete diets.

Feed conversion The efficiency of farmed animals to incorporate given feed into biomass. Feed conversion is usually expressed in terms of the feed conversion ratio of weight of feed provided to fish/shellfish flesh biomass harvested. The ratio is affected by the relative moisture content of both feed and aquaculture product as well as by the metabolic characteristics of the farmed species, farming techniques, and husbandry.

Life cycle assessment (LCA) Environmental framework incorporating the whole production chain with the intention of (1) producing an inventory of the economic and environmental inputs and outputs to each stage of a product/service life cycle and (2) quantifying a subset of the environmental impacts potentially associated with those flows using standardized impact assessment methods.

Seed A term used to describe eggs, larvae, postlarvae, or juveniles (fry and fingerlings) stocked into aquaculture production systems.

Spawner Mature individual of a stock responsible for reproduction.

Introduction

Aquaculture, the aquatic counterpart of agriculture, has grown rapidly in recent decades, and today it produces almost as much fish and shellfish as fisheries. Aquaculture is the main means for obtaining more food from our aquatic environments in the future. Impacts of aquaculture on biodiversity arise from the consumption of resources, such as land (or space), water, seed, and feed, their transformation into products valued by society, and the subsequent release into the environment of greenhouse gases and wastes from uneaten food, fecal, and urinary products, chemotherapeutants as well as microorganisms, parasites, and feral animals. Negative effects may be direct, through release of eutrophication substances, toxic chemicals, the transfer of pathogens diseases and parasites to wild populations stock, and the introduction

of exotic and genetic material into the environment, or indirect through loss of habitat and niche space and changes in food webs. Today, large quantities of fish are caught to produce fishmeal and fish oil – an important source of ingredients for protein and fatty acids in feeds for many fish and shrimp species – which besides being a questionable usage of a valuable food resource also may contribute to the high fishing pressure on some stocks with potential negative consequences for marine food webs. Despite advances being made within the feed industry, resulting in decreased feed conversion ratios and development of suitable alternatives to fish resources, the aquaculture industry's use of global fishmeal and fish oil increased three-fold between 1992 and 2006 (Hasan and Halwart, 2009).

The life cycles for most aquaculture species have been successfully closed but the culture of some, especially marine,

farmed fish, and shrimp, is still partially dependent on the capture of larvae, postlarvae, or gravid females from the wild. This can result in both over-fishing and bycatch, representing losses to capture fisheries and biodiversity. Large areas of critical habitats such as wetlands and mangroves have historically been lost due to the siting of aquaculture developments and pollution, resulting in reduced biodiversity and recruitment to capture fisheries. Today the values of coastal wetlands are better recognized and regulations make it difficult for large-scale aquaculture development in sensitive coastal areas (e.g., mangroves, seagrass beds) in most countries.

The magnitude of biodiversity loss from aquaculture development generally increases with scale, intensity of resource use, and net production of wastes. It is also very much dependent on the location of production site, species being cultured, the aquaculture system being used, method of cultivation and management, and the aquaculture site. In some cases aquaculture may also increase local biodiversity, for example, when ponds are constructed in dry areas, through restocking activities and from integrated aquaculture. Its role in maintaining cultural diversity must also be acknowledged.

Aquaculture Development and Practices

The farming of aquatic plants and animals is several thousands of years old. Nevertheless, it must be regarded as a largely post-World War II phenomenon. In 1950, global farmed fish and shellfish production was approximately 2 mmt (million metric tons) and largely confined to areas of Asia. During the last three decades, aquaculture production has increased by approximately 7–11% per year. Production for 2008 was 33.9 mmt of finfish, 5 mmt of crustaceans, 13.1 mmt of mollusks, and 15.7 mmt of aquatic plants (FAO, 2010). Fish produced by aquaculture now accounts for half of all fish directly consumed by humans. More than 400 species of fish and shellfish are farmed; the range includes giant clams that obtain most of their nutrients from symbiotic algae, various species of carps that are largely herbivorous, and

Atlantic salmon and marine fish species that are carnivorous (Table 1).

Aquaculture typically involves the enclosure of a species in a secure system under conditions in which it can thrive. Interventions in the life cycle range from exclusion of predators and control of competitors (extensive aquaculture) to enhancement of food supply (semi-intensive) or even the provision of all nutritional requirements (intensive). Intensification of production also implies increasing the number of individuals per unit area, which decreases the local demand for land/sea space but instead requires greater use and management of inputs and a greater reliance on technology and fossil energy.

Aquaculture is an economic activity that uses and transforms natural aquatic resources into commodities valued by society and in so doing it may impact on biodiversity, essentially due to the consumption of resources, the transformation process (aquaculture), and the production of wastes (Naylor *et al.*, 2000; Boyd *et al.*, 2005; Diana, 2009) (Figure 1). Looking at the diversity of farming systems it is easy to appreciate that the biophysical impacts of aquaculture activities, that is, magnitude and spatial scale, vary enormously. Technical and economic inputs, such as construction materials and energy, in many traditional aquaculture systems form only a small part of the inputs needed. The main and critical inputs are instead natural resources and to some extent also labor. Together with ecosystem services these ultimately determine the limits for the local and global expansion of aquaculture. The magnitude and type of resource use and impacts of aquaculture are, however, very much dependent on species cultured, farming system, intensity of farming methods, and management.

Production practices and their impacts on aquatic ecosystems vary widely across species. Mollusks such as scallops and mussels are generally farmed along subtidal or intertidal coastlines where wild-caught or hatchery-reared seed are grown in bags set on the sea bottom or on stakes and suspended ropes. The animals rely entirely on prevailing supplies of plankton and organic particles for food. Even though no feed is added, large densities of filter-feeding organisms may cause reversible local organic accumulation, resulting in

Table 1 Summary of the most important aquaculture species groups, farming systems and methods in terms of production

Group	System	Method of culture
Plants		
Euclidean, Kappaphycus, Gracilaria, Gelidium, Caulerpa	Stakes, rafts, long-lines, beds	Extensive
Bivalve molluscs		
Oysters (<i>Crassostrea</i> spp.), mussels (<i>Mytilus</i> spp.), Cockles, Abalone	Rafts, long-lines, stakes, beds, tanks	Extensive
Shrimps and prawns		
Shrimps (<i>Penaeus</i> spp., <i>Litopenaeus vannamei</i>)	Ponds	Extensive, semi-intensive, intensive
Marine, brackishwater fish		
Milkfish (<i>Chanos chanos</i>), yellowtail (<i>Seriola</i> spp.), groupers (<i>Epinephelus</i> spp.), mullets (<i>Mugil</i> spp., <i>Liza</i> spp.), cobia (<i>Rachycentron canadum</i>)	Ponds, cages,	Semi-intensive, intensive
Freshwater/diadromous fish		
Chinese carps, Indian carps, tilapia, Atlantic salmon (<i>Salmo salar</i>), trout, catfish	Ponds, cages, tanks	Extensive, Semi-intensive, intensive

Figure 1 Diagram illustrating the principal direct and indirect effects from aquaculture on biodiversity, through the use of resources and the generation of wastes. It should be noted that additional impacts associated with specific culture systems exist, and that as impacts resulting from management are not included. Note that other impacts being specific to system. Details are given in the text.

negative effects on benthic diversity, and possibly also, if farmed in large quantities, impact on pelagic plankton communities. A range of systems – ponds, tanks, or cages – are used to farm finfish. The majority of carp and other freshwater species farmed in the tropics and subtropics are herbivores/omnivores and are grown in ponds fertilized by supplemental feeds. In contrast, most diadromous and marine finfish, including both tropical and temperate species, are farmed intensively in floating net cages and are to a large extent reliant on nutritionally complete fishmeal and fish oil-based diets. For some marine fish species farmed mainly in Southeast Asia, including also freshwater species like *Pangasius* catfish (e.g., in Vietnam) large amounts of fish, so-called trash fish, are being used directly as feed (Huntington and Hasan, 2009).

Penaeid shrimps, dominating crustacean farming, are reared in semi-intensive or intensive coastal pond systems. The shrimps depend mainly on formulated pellet feeds, aeration to replenish dissolved oxygen, and pumped seawater to dilute pollutants and flush out harmful metabolites. Shrimp postlarvae are either derived from captured wild spawners/broodstock or directly collected from the sea – something that is true also for the freshwater shrimp *Macrobrachium* (Ahmed *et al.*, 2010).

The aquaculture process in itself may affect biodiversity as a result of disturbance through increased road and boat traffic. High densities of farmed fish and food often attract predators and scavengers such as wild fish, gulls, and seals. These can come into conflict with farmers and may be killed, either accidentally (entanglement in nets) or deliberately (shooting and trapping), or if they become established they may displace sensitive local species (Boyd *et al.*, 2005).

Feed Resources

Extensive or semi-intensive aquaculture, for example, pond farmed carps and filter-feeding bivalves, depends either on natural production or agricultural wastes and some generally locally made feed. Filter feeders like mussels do not depend on addition of feed; however, very dense farming of mussels and bivalves in semi-enclosed coastal areas may in exceptional

cases reduce fisheries stocks by shortening the linkages comprising the food web. In Rio Arosa, Spain, for example, overgrazing of the phytoplankton population by filter-feeding mussels resulted in zooplankton starvation and the subsequent collapse of the sardine fishery (GESAMP, 1991).

Nutrient-rich materials added to stimulate the growth of algae and other food items, and on-farm feeds, based largely on cheap, locally available agricultural by-products, augmented by household scraps and perhaps small amounts of fishmeal, are used to supplement the food in extensive ponds. However, in the intensive production systems that predominate in temperate aquaculture, and are increasing in the tropics, the farmed animals are to varying degrees reliant on nutritionally complete commercial feeds containing fishmeal and fish oil. Marine fish species and shrimps have high demand for fish resources in the feed but also freshwater fish species like carp, tilapia, and catfish, which being herbivores or omnivores, are also increasingly being farmed using formulated feeds containing various percentage of fishmeal and fish oil (Tacon and Metian, 2008).

Diets for salmonids, seabass, sea bream, and other carnivores are largely composed of fishmeal and fish oil. Although it may be possible to replace much of the fishmeal used in intensive fish diets with proteins of plant origin (e.g., oilseeds) (Stickney *et al.*, 1996; Hasan and Halwart, 2009), requirements for essential amino acids, especially cystine and methionine, is still to a large extent being met by fishmeal. It remains to be seen whether commercial plant protein-based diets can be developed in an industry in which the product is competing with many others for customer attention and in which profit margins are increasingly being squeezed. Depending on the source and inclusion rate, oilseed meals can compromise palatability, growth (Stickney *et al.*, 1996), and profitability. Any decrease in palatability or diet digestibility may aggravate waste loadings to the environment. The issue of fish oils is even more pressing than that of fishmeal (Naylor *et al.*, 2009). Aquatic carnivores are poor at using carbohydrate to supply energy requirements, relying instead on protein and lipid (Cowey and Sargent, 1977). The substitution of fish oils with vegetable oils in freshwater carnivorous or omnivorous

fish diets is more straightforward than for marine and diadromous carnivorous species, such as Atlantic salmon, which require n-3 highly unsaturated fatty acids. Progress has been made with respect to alternative sources like rapeseed and linseed as well as synthesis of n-3 fatty acids, which can supplement various feeds while still resulting in acceptable high growth and quality (Naylor *et al.*, 2009).

Currently, approximately one-third of the total harvest from capture fisheries is destined for nonfood use, of which most is used to produce fishmeal and fish oil for aquaculture (Tacon and Metian, 2009) (Figure 2). Fish species being used for reduction to fishmeal includes species such as Peruvian and Japanese anchovy, Blue whiting, Atlantic herring, chub mackerel, Chilean jack mackerel, capelin, European pilchard (Kaushik and Troell, 2010). Many fishes exploited for feed are fast growing opportunistic species and therefore can sustain a heavy fishing pressure. However, production of some of these species is also constrained by climatic variability associated with El Niño–Southern Oscillation events (FAO, 1997; NRC, 1999) and impacts on marine biodiversity from intensive fishing on pelagic forage fish species, including reduction of available food supplies for marine predators and valuable

species consumed by humans, have not been studied in a systematic way (Smith *et al.*, 2011). In Europe, the crash of North Sea capelin and herring stocks has been attributed to over-fishing and this may have caused depletion of other wild fish stocks (e.g., cod) and the starvation of seals and seabird chicks (Vader *et al.*, 1990; Naylor *et al.*, 2000). Declining capelin populations in the western Gulf of Alaska are implicated in the decrease of harbor seal and sea lions in the early 1980s (Hansen, 1997). A strong interaction between anchovy and seabird and mammal populations has also been well documented for the Peruvian upwelling system (Pauly and Tsukayama, 1987). Recent focus on fishing for krill near Antarctic for aquaculture feeds may result in negative ecosystem consequences for a system that is not yet fully understood.

Low value fish, that is, so-called “trash fish” (from rivers, lakes, and the sea) has increasingly been used directly as feed in aquaculture, especially in Asian countries, with implication for both biodiversity and food security (Huntington and Hasan, 2009). Despite significant progress being made on reducing inclusion of fishmeal and fish oil in feeds, and finding alternative feed ingredients (e.g., plants and microorganisms)

Figure 2 Ecological links between aquaculture and capture fisheries. Thick blue lines refer to main flows from aquatic production base through fisheries and aquaculture to human consumption of seafood. Numbers refer to 2006 data and are in units of megatons (million metric tons) of fish, shellfish and seaweeds (green). Thin blue lines refer to other inputs needed for production. Hatched red lines indicate negative feedbacks. Flows to, for example, pond aquaculture from cage aquaculture also exist as used feed fish generates surplus of fishmeal (not in Figure) (Graphic outline from Naylor *et al.*, 2000. Data from Tacon AGJ and Metian M (2008) Global overview on the use of fish meal and fish oil industrially compounded aquafeeds: Trends and future prospects. *Aquaculture* 285: 146–158).

(Tacon and Metian, 2008; Naylor *et al.*, 2009), some intensive and semi-intensive aquaculture systems use more fish protein to feed the farmed species than is ultimately harvested. Also, the increase in global aquaculture production has resulted in a net increase in total demand for fish resources in aquaculture and it is estimated that 68% and 98% of global fishmeal and fish oil, respectively, were utilized by the aquaculture sector in 2006 (Tacon and Metian, 2008; FAO, 2010). Alternatives to fishmeal and fish oil include soy meal, soy oil, livestock co-products, vegetable oil, single cell, and other locally available resources (e.g., snails in Bangladesh). Other commonly used feed ingredients for many freshwater fish species include rice and wheat bran, maize gluten meal, and cassava meal (Naylor *et al.*, 2009).

In 2006, 74.2% of total aquaculture production was of species feeding low in the aquatic food chain, including aquatic plants, filter-feeding molluscs, and herbivorous and omnivorous finfish species. Farming of fish species such as carps, tilapia, and catfish dominates production and even though this production is increasingly based on fish resources, it results in a net production of fish. This will, however, change if farming methods continue to intensify and increasingly utilize higher quality fishmeal-based feeds or feeding with low-valued fish (Tacon and Metian, 2009). For other fish species, for example, marine and some diadromous species (e.g., salmon), production requires more fish as feed than is ultimately produced. For example, approximately 3.4 kg of wild fish is used to produce 1 kg of farmed salmon (estimated IFFO values for 2010 in Tacon and Metian, 2008). The culturing of such species thus leads to a net loss in fish protein and fish oil.

Human consumption of seafood was 112 mmt in 2006, of which 59 mmt of fish, crustaceans, and mollusks come from capture fisheries, whereas 52 mmt are from aquaculture (Tacon and Metian, 2008; FAO, 2010) (Figure 2). Total capture fisheries was 99 mmt but 7 mmt of this is discarded as bycatch and 33 mmt being used for fishmeal production or as direct feed, often for aquaculture (Tacon and Metian, 2009; FAO, 2010). An additional few mmt of processing scraps from aquaculture and fisheries are also converted into fishmeal. Thus, 64% of total fish resources are being transformed to fishmeal and fish oil or used directly as animal feeds. Twenty-four mmt are currently used in aquaculture, the rest being used for chickens, pigs, and other animals, as well as health food supplements (approximately 9 mmt) (Tacon and Metian, 2009). However, even though farming efficiency improves and substitutes for fish in feeds are being developed, an increasing proportion of fish resources will probably be used for aquaculture feeds as supplies are unlikely to expand and as aquaculture production continues to grow (and demand for higher trophic level species) and production methods of pond fishes in major producer countries such as China intensify (Rana *et al.*, 2009).

Land, Water, and Energy

Land is needed to build fish or shrimp ponds or establish tank-based operations, whereas fish cages, pens, and mussel and seaweed farm operations occupy areas of lakes, rivers, and

the sea. Fish ponds are usually sited in agricultural land and this arguably contributes positively to the floral and faunal diversity of agriculture landscapes. However, unproductive, boggy areas of agricultural land have often been used, and since such boundary ecosystems, or ecotones, may serve as reserves for species in areas otherwise surrounded by monocultures of crops, this may in fact reduce biodiversity. Land is becoming scarcer and the increasing competition with other users, for example, agriculture and urban development, puts pressure on aquaculture to minimize appropriation of land. This has promoted the intensification of farming systems with high stocking densities, resulting in higher dependence on external concentrated inputs, for example, feed, energy, and chemicals. On the positive side, less land is needed per metric ton of fish production and the resultant more concentrated wastes are also more amenable to treatment. However, if treatment is not done the environmental impacts may be severe.

Large areas of tropical coastal wetlands and mangroves have historically been converted to fish and shrimp ponds, resulting in impoverished biodiversity and recruitment to fisheries, with consequences for local communities and regional economies (Rönnbäck *et al.*, 2002; Walters *et al.*, 2008). Thus, since the 1400s, hundreds of thousands of hectares of mangroves have been transformed into milkfish ponds in Indonesia and the Philippines. In recent decades, shrimp farming has been responsible for a significant share of the conversion of coastal and supratidal areas, for example, 102,000 ha of mangrove forests in Vietnam during 1983–1987 (Tuan, 1997) and 65,000 ha in Thailand during 1961–1993 (Menasveta, 1997). When the full range of ecological effects associated with mangrove habitat loss are accounted for, the net production in fish and shrimp aquaculture may be negative (Rönnbäck, 1999; Barbier *et al.*, 2008). Coastal ecosystems, such as mangroves, seagrass beds, and coral reefs, provide habitats and nursery areas for many fish and invertebrate species caught in coastal and offshore fisheries (Robertson and Duke, 1987). A positive relationship between commercial fish/shrimp landings and mangrove area has also been documented throughout the tropics (Pauly and Ingles, 1986; Rönnbäck, 1999). To identify and value total commercial and subsistence fisheries catch supported by mangroves, economic analyses must take into account: (1) the large number of resident and transient species that utilize mangroves as habitat; (2) the direct and indirect subsidies of shrimp trawlers and mangroves, respectively, to total fisheries catch; and (3) the aquaculture industry's dependence on inputs like seed, broodstock, and feed (Rönnbäck, 1999; Walters *et al.*, 2008). By acknowledging these support functions, the potential life-support value of mangroves to fisheries is in the order of 1–10 mmt of fish and shellfish per hectare per year (first sale value $\approx$ \$1000–10,000 US in developing countries) (Rönnbäck, 1999). In addition, mangroves also harbor a wide array of non-marketed fish, crustacean, and mollusk species, whose subsistence harvest constitutes an important protein source for coastal communities. Moreover, mangroves are closely linked to habitat conditions and associated biodiversity of coral reefs and seagrass beds through the biophysical interactions in the coastal seascape (Moberg and Rönnbäck, 2003; Nagelkerken, 2009). Almost one-third of the

world's marine fish species are associated with coral reefs, and fish catches from reefs contribute to approximately 10% of human fish consumption at a global level and much higher in developing countries (Weber, 1993; Moberg and Folke, 1999).

Aquaculture requires large amounts of water to physically support the farmed animals, replenish oxygen, and remove wastes. The impacts of aquaculture on the quantity and quality of water resources have direct impacts on associated aquatic biodiversity. Large amounts of water pass through cages and pens (in the sea or lakes) but there is no net removal from the system. It is important to distinguish between water consumption and water withdrawal, the former implying that water diverted from streams, rivers or aquifers lost through evaporation or seepage, while in the latter water is returned to the environment to be reused or restored (Verdegem and Bosma, 2009). Consumptive water use in aquaculture has mainly impacted on the reduction in downstream freshwater flows and groundwater resources (Boyd *et al.*, 2005). In land-based systems, aquaculture not only borrows water, returning it in a more degraded form, but also consumes it or accelerates its loss from surface to groundwater or the atmosphere (Boyd, 2005; Boyd *et al.*, 2005). Thus, by creating ponds, especially in areas of poor (sandy/loam) soils or high temperatures, evaporation and seepage are increased and 1–3% of the fish pond volume may be lost in this way each day (up to 45 m³ kg⁻¹ produced in ponds) (Verdegem *et al.*, 2006; Dugan *et al.*, 2007). Such losses may be particularly significant in arid or semi-arid areas of the world, such as Israel, where fish pond design and management practices have had to be changed in order to reduce surface water losses. Conversely, the incorporation of a fish pond into small rural farms has been shown to improve water conservation (i.e., creating a water reservoir) (Dey *et al.*, 2007). In addition, recent analysis shows that indirect freshwater consumption in aquaculture can be significantly higher than direct consumption (Verdegem *et al.*, 2006). This is because formulated feeds indirectly consume large quantities of water through crop and livestock production. About 1.2 m³ of water is needed to produce 1 kg of grain. Fish and crustaceans require less grain compared to other terrestrial animal production, and even if water consumption through feed is large total freshwater consumption by aquaculture is small compared to, for example, agriculture. Total freshwater use depends on system and practice but it has been estimated that the 8,750,000 ha freshwater and 2,333,000 ha brackish water ponds for aquaculture consume approximately 429 km³ yr⁻¹ (16.9 m³ kg⁻¹), which represents only 3.6% of flowing water globally (Verdegem and Bosma, 2009).

Intensification of the aquaculture sector has led to an increasing dependence on external energy inputs throughout the production chain. Feed is commonly the main energy demanding source for fed aquaculture systems, while pumping, water purification and aeration may contribute significantly to 'closed' systems (Troell *et al.*, 2004; Henriksson *et al.*, 2012). Transportation, in turn, often accounts for a surprisingly small fraction of energy inputs (less than 1% for Norwegian salmon) (Pelletier *et al.*, 2009) while holding aquaculture products at warehouses can be an energy consumption hotspot for live organisms such as mussels and abalone (Iribarren *et al.*, 2010). Cumulative energy demand has been shown to

provide a good indicator of both carbon footprint and ecological footprint while the true environmental consequences related to energy production depend largely on the energy carrier and country of production (Huijbregts *et al.*, 2010).

Wild Capture of Larvae and Spawners

The farming of shrimp and fish depends on larvae collected from the wild or reared in hatcheries from eggs of wild or farmed broodstock or spawners (Figure 2). Although most of the aquaculture industry today relies on hatchery-produced fry and fingerlings derived from parents bred in captivity, some tropical marine fish and shrimp culture still depends on capture of wild broodstock or juveniles (i.e., India, Bangladesh, The Philippines, Indonesia, etc.). Besides adverse effects on wild stocks of the target species, large bycatch of other larvae are killed in the process, representing losses to capture fisheries and biodiversity (Naylor *et al.*, 2000; Ahmed *et al.*, 2010). The quantities of bycatch associated with such wild catches are directly proportional to the natural abundance of the target species for culture. For example, milkfish *Chanos chanos* constitute only 15% of total fry in inshore collections by seine net (Bagarinao and Taki, 1986). The annual utilization of approximately 1.7 billion wild fry for stocking in Philippine milkfish ponds in the end of the 1990s (Bagarinao, 1997; 1998) corresponded to a loss of nearly 10 billion fry of other fish species. Many shrimp and prawn ponds in India and Bangladesh are still to a large extent dependent on stocking with wild-caught seed of *Penaeus monodon* and *Macrobrachium rosenbergii* (Hoq *et al.*, 2001; Ahmed *et al.*, 2010). The peak period for this fishery reached one billion *P. monodon* seed collected annually in southeast Bangladesh (Dev *et al.*, 1994). Up to 900 fish and other shrimp fry species are discarded for every targeted shrimp being collected from estuarine and coastal waters in Bangladesh (Ahmed *et al.*, 2010). This is sufficiently large to potentially cause major impacts on biodiversity and capture fisheries production, but to date remains unstudied.

The development of hatcheries for cultured shrimp and marine fish species (e.g., milkfish) has reduced dependence on wild seed. However, it has also increased the demand for wild-caught mature (spawners) and immature (broodstock) shrimp adults (Rönnbäck *et al.*, 2003). For example, because the species is rare, wild collection of *P. monodon* broodstock and spawners can lead to large amounts of bycatch, with consequences for fisheries and biodiversity.

Impacts of Wastes, Chemicals, Diseases, and Feral Animals

The term 'wastes' in the current context is used to mean not only food, fecal and urinary products, and chemicals, but also microorganisms, parasites, and feral animals that may be introduced and subsequently thrive in aquaculture environments which may subsequently be released to the wider environment (Figure 1) (Beveridge, 2004; Hargrave, 2005). The release of uneaten food and fecal and urinary wastes may lead to eutrophication and oxygen depletion, the magnitude of the

impact depending on the type and size of operation and the nature of the site, ecosystem characteristics and assimilative capacity. Local effects from nutrient release into marine ecosystems, from coastal and near-shore intensive aquaculture operations, especially shrimp pond and fish cage farming, have been well studied (Islam, 2005). For example, eutrophic conditions from uncontrolled fish pen and cage operations in Pangasinan, Philippines, included increased ammonia, nitrate, nitrite, and phosphate concentrations, and low dissolved oxygen levels, leading to a major fish kill in 2002 valued at US\$ 9 million (San Diego-McGlone *et al.*, 2008).

Sediment impacts associated with cage farming can be severe, resulting in anoxic sediments where fauna been lost. The effect on sediments is, however, mainly local and biodiversity will return a few years after production stops. However, studies documenting more large scale and long-term ecosystem changes from excessive nutrient emissions are few. Avoiding release of wastes, thereby minimizing environmental impacts, has been one of the drivers toward land-based 'closed' production systems. This has, however, come at the price of higher energy dependency (Henriksson *et al.*, 2012). However, semi-intensive, extensive, traditional, polyculture, and integrated systems generally assimilate much wastes internally (Beveridge, 2004; Edwards, 2009; Troell, 2009) resulting in fewer wastes being discharged to surrounding ecosystem.

Chemotherapeutants, including antimicrobial compounds and pesticides, are mainly used in intensive fish and shrimp cultures to control bacterial, fungal, and parasitic diseases. In shrimp farming, prohibited chemicals may be used due to lack of legislation or poor implementation of regulations. Farmers also use a range of vitamins, immunostimulants, disinfectants, and chemotherapeutants and employ chemicals for pond soil and water treatment (Gräslund and Bengtsson, 2001). The impacts of many of these chemicals are largely unknown. The release of antibiotics into the environment can affect microbial biodiversity and antimicrobial drug resistance but has reduced hugely in the farmed salmon industry due to the introduction of vaccines (Adams, 2009). Controls on use are increasingly strict, especially for aquaculture products aimed at the European and North American market (Beveridge *et al.*, 2010), but the controls target mainly the finalized products and not the aquaculture production process.

Impacts of aquaculture operations on biodiversity are strongly linked to introductions of exotic species and strains (Naylor *et al.*, 2001). Worldwide transfers and introductions of the few preferred shrimp culture species, including *P. monodon*, *Litopenaeus vannamei*, and *Marsupenaeus japonicus*, were numerous in the early decades of commercialized farming (Kautsky *et al.*, 2000). Such introductions and transfers may lead to competition with endemic fauna, genetic introgression with local fauna, and introduction of pathogens and parasites (Naylor *et al.*, 2001). Tilapia have had a long history of deliberate (for aquaculture and fisheries) and accidental introductions to some 90 countries and territories. However, recent studies suggest that impacts of tilapia introductions in Asia on aquatic ecosystem structure and function have been relatively small and often outweighed by the socioeconomic benefits (Gross, 1998; Arthur *et al.*, 2010). Atlantic salmon have escaped from culture facilities both within the geographic range of wild Atlantic salmon as well as in Pacific waters, and are

now found as far north as the Bering Sea and as far south as Chile. Increasing evidence suggests that escapes may have direct genetic impacts on wild populations through hybridization (Walker *et al.*, 2006). Larger numbers of escapes also increase the likelihood of hybridization between feral farmed Atlantic salmon and wild fish in populations that are locally endangered or close to extinction (Slaney *et al.*, 1996; Gross, 1998; Hindar *et al.*, 2006). In addition to consequences for the population gene pool and fitness, there are many potential ecological impacts associated with feral fish. Feral Atlantic salmon may compete extensively with wild salmon species for food and space, disturb native spawning sites, and introduce new diseases and parasites into wild populations (Jonsson and Jonsson, 2006).

The consequence of the large-scale introduction of the shrimp *P. vannamei* into Asia and the Pacific on biodiversity of indigenous cultured or wild shrimp populations is still uncertain as insufficient time and research have been conducted on this issue and there is therefore a need for caution (Briggs *et al.*, 2004). Recent field surveys in the Bangpakong Estuary in Thailand (where this species contributed >99% of total 2007 marine shrimp production) show that the species is persistent in the wild, and the presence of Taura Syndrome Virus (TSV) has been detected in seven local species (Senanan *et al.*, 2010). Moreover, laboratory studies show that *P. vannamei* can tolerate environmental conditions in the estuary and seeks food better than some of the indigenous species. The development of genetically modified species for aquaculture is currently being heavily debated (Kapusinski *et al.*, 2007), and of particular interest is the 'super salmon' that has been developed by Aquabounty and is awaiting approval by the US Federal Drug Administration to be farmed commercially. The animal has a single copy of a DNA sequence that includes code for a Chinook growth gene as well as regulatory sequences derived from Chinook salmon and ocean pout (Marris, 2010).

Numerous wild salmon stocks in Canada and Norway have been infested by sea lice, either through the release of juvenile farmed salmon or large densities of fish cages in coastal salmon migration routes (Krkosek, 2010). The mechanisms and linkages to farmed salmon in Canada, however, is still being debated (Marty *et al.*, 2010).

Diseases are prevalent in many types of aquaculture, especially in highly stocked, intensive production systems, for example, Atlantic salmon, marine fish species, marine shrimp, etc. For example, the introduction of shrimp postlarvae and broodstock from areas affected by the White Spot Syndrome Virus (WSSV) and TSV resulted in the rapid spread of these pathogens throughout most of the shrimp-growing regions in Asia and Latin America, respectively (Kautsky *et al.*, 2000). A native of Asia, where it has caused multimillion-dollar shrimp crop losses, the WSSV has also been detected in wild and cultured shrimp in Texas and South Carolina. The virus was probably introduced by release of untreated wastes from plants processing imported Asian shrimp into coastal waters and by use of imported shrimp as bait in sport fishing or as fresh food for rearing other aquatic species (Lightner *et al.*, 1997). Another major shrimp virus, the Infectious Hypodermal and Hematopoietic Necrosis Virus (IHHNV), was probably introduced to the Americas from Asia through the import of live *P. monodon* in the early 1970s (Lightner *et al.*,

1999). In the Philippines, IHNV prevalence in various wild populations of *P. monodon* has been correlated with intensification of shrimp culture methods and with mangrove status (Belak *et al.*, 1999). Higher incidence of viral infection in wild shrimp has been observed in areas with intensive shrimp farms and severely degraded mangroves.

The multibillion dollar Chilean salmon industry was during 2008 hit by Infectious Salmon Anemia (ISA) virus, resulting in millions of dead salmon and the layoff of thousands of fish farm workers. The main salmon farming areas in Chile are around Chiloe Island and this area is now being contaminated. Salmon producers are therefore reducing farm and fish densities as well as seeking to transfer their businesses further south. Whether the move will be successful or not is uncertain because this area has previously been almost free of farming operations due mainly to its remoteness and concern for the integrity of the seascape. Another factor that may compromise the successful translocation of salmon farming to the south is that the ISA virus already appears to be present in these waters.

In contrast to shrimp and salmon, comparatively few diseases have been reported for carps, tilapia, and milkfish, particularly from extensive and other low-density culture systems. The current trend toward intensification in rearing ponds and cages, however, may create stressful conditions through deterioration of water quality, excessive stocking, and polluted water inflow that predispose the fish to disease. The farming of *Pangasius* catfish in Vietnam has increased rapidly, reaching more than 1 mmt in 2008, and farming is characterized by holding high densities of fish in the ponds, resulting in increased risks for diseases and heavy usage of antibiotics (Phan *et al.*, 2009).

Resource Use and Carrying Capacity – Energy Analysis, Ecological Footprint and Life-Cycle Assessment

To reduce the risk of resource constraints and impacts on biodiversity, a shift to aquaculture production systems that use less valuable resources and emit wastes that do not exceed the assimilative capacity of the environment must occur. There is a need to recognize and manage nature's life support and its provision of ecosystem services, on which economic development and human welfare depends. Besides traditional EIA one way of identifying the broader demands for natural resources and ecosystem services of aquaculture has been to estimate the ecosystem area – the ecological footprint – functionally required to support the activity. When problems beset aquaculture operations, solutions focus on the pond or cage unit, and the fact that the farm is part of a much larger ecosystem with which it interacts is generally not considered. Surrounding ecosystems provide the feed, seed, clean water, and other essential resources and services, including waste assimilation. This unvalued work of nature sets the limits to culture levels without compromising biodiversity or causing pollution or disease problems. The footprint concept has proven to be very useful in illuminating the nonpriced and often unperceived work of nature that forms the basis for economic activities such as aquaculture. It is, however, not a

Figure 3 Ecosystem support areas required to sustain a semi-intensive shrimp farm in a coastal mangrove area of Columbia/ square meters of support area needed per square meter of pond area.

detailed tool for measuring environmental capacity or sustainability in aquaculture, but an excellent tool for communicating human dependence on life-support systems.

An illustration of how the footprint concept can be used for aquaculture is provided by Larsson *et al.* (1994). They estimated the spatial ecosystem support, or footprint, for a semi-intensive shrimp farm in a coastal mangrove area in Colombia. Support included food inputs, nursery areas, clean water, as well as waste processing and the support area was 35–190 times the surface area of the farm (Figure 3). The details of the footprint include: mangrove nursery area required to produce the shrimp seed for stocking – up to 160 times the pond area; if located close to the farm, the same mangrove area could also supply natural food inputs ($4.2 \text{ m}^2 \text{ m}^{-2}$ shrimp pond area) and absorb polluting nutrients ($2\text{--}22 \text{ m}^2 \text{ m}^{-2}$ pond area) in the farm effluents; feed pellets, a major input to a shrimp farm, needed a marine area of 14.5 m^2 to produce the fish, and an additional agricultural area of 0.5 m^2 for the agriculture ingredients used in feed pellets; 7.2 m^2 was needed to provide clean lagoon water to the ponds; and $0.8\text{--}2.5 \text{ m}^2$ of forest area per square meter shrimp pond area was needed to sequester the CO₂ associated with fossil fuel consumption at the farm.

Footprint size changes with farming intensity, that is, a higher stocking density requires more food inputs and produces more wastes. However, less intensive production operations stock lower densities of species and thus require larger areas to produce the same biomass of produce. Pressure on local ecosystems can be reduced to some extent by importing some inputs (e.g., feeds) from other areas and by investing in shrimp hatcheries. Although producing seed in hatcheries considerably reduces shrimp and fish larvae bycatch that would otherwise be recruited populations exploited by fisheries, it also increases demand for wild-caught spawners and broodstock (Rönnbäck *et al.*, 2003). Other ecosystem services, however, such as clean water supply and waste assimilation, must be located close to the farming area. Up to a certain level of farming intensity this may pose little problem, but the

whole operation may collapse when the dynamic carrying/assimilating capacity of the local environment is exceeded unless extensive and costly water treatment facilities are built. The footprint concept provides an early warning device when the level of carrying capacity is being approached. Integrated farming technologies that re-circulate resources and wastes within the farm may be one way of reducing the footprint (Troell, 2009).

Aquaculture has directly contributed to the loss of important ecosystem functions (and biodiversity) through land and seascape transformation, and also more indirectly through, for example, pollution. However, aquaculture has also enhanced provisioning services, both in the agriculture

landscapes and in the seascape, thus leading to improved welfare through livelihood diversification. Aquaculture can be a viable substitute for some sectors of today's terrestrial animal production (i.e., as an important source of micronutrients and animal-based protein and lipids), proven to be highly resource consuming (e.g., beef feedlot systems). The question is how to balance the negative and positive consequences from aquaculture development. The landscape and seascape are today increasingly being managed for multiple functions and services in addition to provision of food and fiber, and this requires the integration of ecological and socioeconomic research, policy innovation, and public education. The recently developed 'Ecosystem approach to aquaculture' (FAO,

Figure 4 Illustration of system boundaries being identified in Life Cycle Analysis of an aquaculture production system.

2010) is an example of a broader systematic perspective on aquaculture development. This is a 'strategy for the integration of the activity within the wider ecosystem in such a way that it promotes sustainable development, equity, and resilience of inter-linked social and ecological systems', and could potentially force changes in human behavior with respect to understanding ecosystems functioning and the need for developing institutions capable of integrating different sectors at multiple scales.

Life cycle analysis (LCA) is a standardized eco-efficiency measurement framework that is increasingly being used to build inventories and estimate one or several environmental impacts in aquaculture (Pelletier *et al.*, 2007; Henriksson *et al.*, 2012). LCA identifies system boundaries at the broadest scale, both temporal and spatial, and is a much more quantitative tool than Ecological Footprints (Figure 4). Thus, the width of environmental impacts that can be measured allows for more detailed estimates of the environmental interactions. Climate change, habitat change, pollution and overexploitation are impact categories commonly entailed within the LCA framework (Guinée, 2002), addressing all major drivers, except invasive species, for biodiversity loss, identified by the Millennium Ecosystem Assessment (2005).

Integrated Aquaculture

Integrated aquaculture may offer opportunities for the efficient usage of water and utilization of nutrients, and increased productivity and profits, providing in a single package practical and creative solutions to some problems of waste management and pollution (Neori *et al.*, 2004). Thus, the resulting environmental impacts from aquaculture and various resource limitations (water, feed, energy, etc.) may find their solutions in integrated cultivation techniques (Troell *et al.*, 2004). Traditional inland aquaculture, comprising diverse systems that use on-farm or locally available resources, still dominates in Asia, but they are increasingly being replaced by industrial-based aquaculture technologies (Edwards, 2009). Traditional polyculture/integrated systems make efficient use of inputs and generate less waste, thus adding to net food supplies locally and regionally at relatively minor environmental and social expense. Traditional pond cultures of herbivorous fish species (e.g., carps in China) have been viable for centuries and their existence is the proof of sustainable integrated farming systems. Here, raising poultry and livestock is integrated with fish farming, and the principal linkages between the systems are animal manure and other agriculture waste products. Compost is used to fertilize the pond water for proliferation of natural organisms as natural feeds for fish from juvenile to adult. However, despite its environmental advantages the increased global demand for food cannot be met by traditional extensive production systems (due to demand on space and to low productivity). Even though technological development and improved management has resulted in increased efficiency and environmental performance of some intensive single species aquaculture systems, we need to ask what information embedded in traditional integrated systems might be useful for aquaculture development. This information could then be added to recent research on

integrated aquaculture systems. Integrated aquaculture is certainly not a panacea for aquaculture development, but should be looked upon as one potential approach among many others facilitating sustainable development.

The concept of ecological engineering has gained interest in an aquaculture context, with negative environmental effects being remedied by species integration for nutrient trapping or recirculation. The recent development and promotion of integrated aquaculture in coastal areas has focused on modern integrated approaches, mainly from temperate and subtropical regions (China, Canada, South Africa, the Mediterranean Sea, i.e., IMTA systems (Integrated Multi-trophic Aquaculture)) involving integration of fish, seaweeds, crustaceans, and mollusks (Chopin *et al.*, 2002, 2008; Neori *et al.*, 2004;). Such systems try to tackle the throughput characteristics of many farming systems, in which large amounts of wastes are released to the environment. Thus, in addition to output of particulate wastes, aquaculture also releases dissolved nutrients, and generally less than one-third of the nutrients added through feed will be removed through harvest in intensive fish and shrimp farming (Hargrave, 2005; Islam, 2005). Treatment of effluents usually involves a high degree of technology, and therefore high costs, which implies that release of untreated water is the rule rather than the exception (especially in many developing countries). Besides the improved environmental performance, the benefits from integration include economic gains resulting from co-production of different products.

Tropical integrated mariculture systems involve various types of polyculture, sequential integration, temporal integration, and different integration with mangroves (Troell, 2009). An example of the latter is the use of mangroves as biofilters to process effluents from aquaculture ponds. Results from the central Philippines indicate that 1.8–5.4 ha of mangroves are needed to assimilate nitrate wastes from 1 ha of shrimp pond (Primavera *et al.*, 2007). Mangroves and aquaculture are not necessarily incompatible and guides for responsible use of mangrove areas for aquaculture have been developed (Bagarinao and Primavera, 2005; Primavera *et al.*, 2009). However, any development of aquaculture within or nearby mangroves needs to be carefully evaluated to identify net benefits and impacts on environment, biodiversity, ecosystem services, and implications for a variety of stakeholders.

Conclusions

Since the principle of aquaculture is to reroute flows of energy and matter from the ecosystem into those species that we culture, aquaculture, like agriculture, will always affect the environment to some extent. This interaction and alteration of supporting environment is unavoidable, but it should not be done in a fashion that results in the capacity of ecosystems to sustain social and economic development to be diminished. Recent research has revealed that aquaculture systems are strongly coupled to nature's subsidies and services to sustain production, and for many species this subsidy expands beyond the local to the global scale.

Conversion of ecosystems, the extraction of feed resources, collection of larvae and broodstock, spread of exotic species, diseases and effluents, may all add to a spiral whereby total

fish supplies are reduced over time. Thus, the real challenge for aquaculture is to develop farming practices that are in tune with ecosystem processes and functions in a fashion that enhances aquatic food production. There is great potential to develop techniques that work with nature's dynamics. There is also potential to redirect unsustainable modes of production into practices that contribute to and enhance nature's support capacity not only for aquaculture but also for other human activities dependent on aquatic ecosystems. There is no doubt that the aquaculture sector will move in this direction. Governmental policies and institutional frameworks are required that can make such a transition possible. The internalization of the costs of deterioration of supporting areas caused by farming will create incentives for the industry to take a more sustainable path (Folke *et al.*, 1994). This should of course be something that all food production systems (i.e., fisheries, crop, and animal agriculture) strive towards.

The role of the consumers may be critical in shaping farm management practices. Aquaculture products are increasingly traded through multinational supermarkets that are highly responsive to customer opinion and demands. If farmed aquatic foods become associated in the public's mind with poor environmental management and its direct effects on biodiversity, then supermarkets may well refuse to stock the produce. This is today a reality and many labeling schemes are under development (e.g., Aquaculture Dialogue, WWF).

Glossary

Biodiversity The diversity of genes, species, communities, and ecosystems.

Connectivity The connectedness of habitat, land cover, or ecological processes from one location to another, or throughout an entire landscape.

Countryside biogeography A field aimed at understanding the diversity, distribution, and conservation of species in agricultural and other human-modified landscapes.

Ecosystem disservices Functions or processes provided by ecosystems with a negative impact on people.

Ecosystem functions Functions or processes provided by ecosystems.

Ecosystem services Functions, processes, and resources provided by ecosystems with benefits for people.

Holistic resource management A philosophy and practice of livestock grazing management, used by a minority of ranchers in Africa, North America, and Australia, attempting to integrate economic, social, and ecological goals.

Land sparing The spatial separation of biodiversity conservation and agriculture.

Landscape A human-defined area, typically ranging in size from approximately 1 to 1000 km².

Landscape heterogeneity The variability in land cover types within a given landscape.

Matrix The dominant and most extensive patch type in a landscape, which exerts a major influence on ecosystem processes.

Native vegetation Plant species growing naturally in a certain region.

Patch A relatively homogenous area within a landscape that differs markedly from its surroundings.

Seminal natural vegetation Near-natural vegetation associations that provide suitable habitat for a large number of native species.

Structural complexity The complexity of the vertical architecture of vegetation, including a ground layer, shrub layer, and tree layer(s).

Article Outline

As the global population continues to increase, ever more land is used for agricultural production. What does this mean for biodiversity conservation? Agricultural land use constitutes one of the greatest threats to biodiversity. A key challenge is to find ways in which agricultural land use and biodiversity conservation can be integrated. A rapidly growing body of research has demonstrated a variety of generic measures that typically help to conserve biodiversity in agricultural landscapes. Such measures include local-scale activities that farmers can undertake and landscape-scale measures which can be encouraged through regional coordination and appropriate incentives. Drawing on examples from around the world, this article provides an up-to-date overview of current knowledge on biodiversity-friendly farming.

Introduction

In 1700, nearly half of the global land surface was free of human settlements or agricultural land use, with the remainder covered by seminatural vegetation, including small-scale agriculture and human settlements (Ellis *et al.*, 2010). Today, the vast majority of Earth's surface has been significantly influenced by human activities. Estimates are that only 25% of land remains in largely natural condition, and 40% is used for the production of crops and livestock grazing (Ellis *et al.*, 2010; Asner *et al.*, 2004; Foley *et al.*, 2005). Together,

cropping and grazing thus account for a vast amount of "farmland." Globally, farmland use is expected to further increase in extent and intensity, with demand for food predicted to double from 2000 levels by 2050 (Tilman *et al.*, 2002).

Traditionally, biodiversity conservation has focused on protected areas (Diamond, 1975; Margules and Pressey, 2000). Although a system of dedicated nature reserves is an important backbone to biodiversity conservation, it has become increasingly clear that reserves alone will be inadequate for biodiversity conservation (Lindenmayer and Franklin, 2002; Tschamtko *et al.*, 2005). Presently, approximately 12% of global land is located in protected areas (Hoekstra *et al.*, 2005), or in other words, well over 80% of land is not formally protected. What happens to this land will shape the future of terrestrial biodiversity to a large extent. Reserves alone are simply too small, not sufficiently connected, and not safe enough from anthropogenic threats such as climate change to provide a viable safeguard for biodiversity conservation on their own (Daily, 1999, 2001; Lindenmayer and Fischer, 2006).

Given the need to look beyond protected areas, there has been a surge of interest in the conservation of farmland biodiversity. The subdiscipline of countryside biogeography seeks to understand patterns of species distribution in human-dominated landscapes, including generic relationships between the characteristics of land use, species composition, and species traits (Daily, 1999; Daily *et al.*, 2003; Horner-Devine *et al.*, 2003; Mayfield, *et al.*, 2005). A key motivation for this subdiscipline is the realization that, especially in the tropics,

there is great potential to integrate biodiversity conservation and agricultural production (Steffan-Dewenter *et al.*, 2007). Not tapping into this potential would mean losing some of the most important remaining opportunities for biodiversity conservation.

A second factor sparking increasing interest in the conservation of farmland biodiversity is that a myriad of species declines has been documented in farmland in a wide range of nations (Attwood, *et al.*, 2009; Brown *et al.*, 2008; Conrad *et al.*, 2006; Kleijn *et al.*, 2009; Murphy, 2003). As a result, government initiatives in many countries now try to foster biodiversity conservation on farmland, including through agri-environment schemes in Europe (Kleijn and Sutherland, 2003; Vickery, *et al.*, 2004; Whittingham, 2007), stewardship payments in Australia (Fischer *et al.*, 2010), or the Conservation Reserve Program in the US (Dunn *et al.*, 1993; Ribaud *et al.*, 1990). Partly in response to biodiversity decline, there is a growing interest in farming practices trying to cater for both biodiversity conservation and commodity production. Examples of such practices include organic agriculture (Batáry *et al.*, in press; Badgley *et al.*, 2007; Hole *et al.*, 2005; Rundlöf *et al.*, 2010), integrated pest management (Fitt *et al.*, 2009; Kogan, 1998), or livestock grazing according to the principles of “holistic resource management” (Stinner, *et al.*, 1997; Savory and Butterfield, 1999).

In this article, the authors provide an overview of generic measures that can be used to make farming more biodiversity-friendly. Although the authors provide a range of specific examples, their goal is to give an overview, rather than offer prescriptive advice for any particular farming system. The article is divided into three sections. The first section outlines a range of local-scale measures that typically benefit farmland biodiversity conservation. The second section documents some existing criticisms of measures to integrate biodiversity conservation and agricultural commodity production. As part of this section, the authors critically appraise a putative alternative solution – namely “land sparing,” which is the spatial separation of biodiversity conservation and agriculture. The third and final section discusses why it is important to move from a local-scale focus to a landscape focus that considers whole farmland mosaics.

Local Measures for Biodiversity-Friendly Farming

Several management actions at the local scale can improve the friendliness of farming operations for biodiversity. The local scale is a useful starting point in many cases, because it is the scale at which individual farmers make management decisions. Most of the management actions discussed in this section target a combination of patterns and processes – for example, by changing a certain landscape pattern (e.g., the retention of native vegetation), certain ecosystem functions are improved (e.g., pollination), which in turn benefits biodiversity as a whole.

Retaining Native Vegetation Adjacent to Farmed Areas

Although some species can persist in intensively farmed areas, many more are able to persist in native or seminatural

vegetation. It follows that retaining such vegetation in areas within or adjacent to farmland benefits farmland biodiversity as a whole. Examples of the benefits of native vegetation for farmland biodiversity abound, and come from all over the world. For example, native bee populations in a range of different ecosystems typically decrease with distance from native or seminatural vegetation (Ricketts *et al.*, 2008) (Figure 1) (Box 1). Similarly, many bird species depend on patches of

Figure 1 Decay in the species richness of pollinators with increasing distance from native or seminatural vegetation, based on a meta-analysis including 23 studies with 16 crops on five continents. Reproduced from Ricketts TH, Regetz J, Steffan-Dewenter I, *et al.* (2008) Landscape effects on crop pollination services: Are there general patterns? *Ecology Letters* 11: 499–515, with permission from Wiley.

Box 1 The value of native and seminatural vegetation for pollinators

Pollinator richness and the rate of flower visitation in a crop generally are affected positively by the amount of native vegetation in the surrounding landscape (Morandin and Winston, 2006), and affected negatively by distance to the nearest patch of such vegetation (Figure 1; for a review see Ricketts *et al.*, 2008). Bees require pollen and nectar, and native vegetation can provide foraging resources for bees at times when there is no crop in flower. Bees have a variety of nesting strategies, for example, some nest in the ground and require undisturbed bare soil, whereas others nest in hollow or pithy stems (Michener, 2000). A range of materials may be used in nest construction including mud, pebbles, resin and plant material. Areas of native vegetation can provide nesting sites and building materials for bees, which are essential for their reproduction.

In intensively used agricultural landscapes there may be little remaining natural vegetation, and this has implications for how to best implement biodiversity-friendly farming. In Californian almond orchards, for example, flower visitation by non-*Apis* insects was greater in orchards with more than 30% natural vegetation within a 1-km radius than in isolated orchards with less than 5% natural vegetation (Figure 2). However, while native vegetation clearly benefits bees in this region, many almond orchards occur in locations with little remaining natural vegetation nearby. In such cases, retaining or creating a seminatural strip of vegetation near the orchard's edge can be beneficial for pollinators. Orchards with such strips had non-*Apis* insects visiting flowers at levels intermediate between those in isolated orchards and those with high surrounding natural vegetation (Figure 2). Hence, while large areas of native vegetation are ideal for pollinator diversity, retaining or enhancing seminatural vegetation can also be beneficial.

native vegetation. In recently cleared landscapes, such as the wheat-sheep belt of eastern Australia, native vegetation is critically important for a wide range of bird species, and land clearing has caused the decline of many woodland birds (Lindenmayer *et al.*, 2010; Ford *et al.*, 2009; Recher, 1999).

In landscapes with a long history of human use, such as agricultural landscapes in Europe, it is often seminatural vegetation (rather than strictly native vegetation) that provides biodiversity benefits. Hedgerows and other vegetated field margins, for example, were originally established to delineate field boundaries (Sklenicka *et al.*, 2009), but now fulfill an important function in providing biodiversity benefits (Figure 2), including for small mammals (Wegner and Merriam, 1979), butterflies (Schmitt and Rakosy, 2007; Harvey *et al.*, 2005), and birds (Wegner and Merriam, 1979; Harvey *et al.*, 2005).

Because a substantial amount of literature on farmland biodiversity and the umbrella concept of “countryside biogeography” has come from recently cleared landscapes, one concern might be that in fact, even with the retention of patches of native vegetation, these landscapes will still continue to lose species for many decades into the future (due to an “extinction debt”; see for example, Robinson (1999), Kuussaari *et al.* (2009)). While this is likely in some landscapes (e.g., southeastern Australia; see Fischer *et al.* (2010)), there are also examples of agricultural landscapes that have long maintained a rich diversity of species, despite ongoing agricultural land use. Examples include the highly diversified agricultural landscapes in the Western Ghats of India (Ranganathan *et al.*, 2008), or the foothills of the Carpathians in Romania (Schmitt and Rakosy, 2007). The landscape-scale

diversity (or landscape heterogeneity) of these areas is likely to be an important safeguard for their rich diversity of species – the authors discuss the importance of landscape heterogeneity for biodiversity below (see Biodiversity-Friendly Farming at the Landscape Scale).

A simple rule of thumb is that more natural or seminatural vegetation leads to more biodiversity. The species-area relationship is one of the few established principles (or laws) in ecology, and applies broadly across many different ecosystems (MacArthur and Wilson, 1967; McGuinness, 1984; Rosenzweig, 1995). However, there will also be species that persist in farmland itself for all or part of their life cycle. Farmland provides critically important resources for such species, such as pollen and nectar for pollinators from mass flowering crops (Winfree *et al.*, 2007). This means that retaining native vegetation should not be the only strategy – what happens on the farmland itself is equally important (Pereira and Daily, 2006).

Maintaining Structural Complexity in Farmed Areas

While natural areas adjacent to farmland provide an important source pool for many species, farmland itself also can provide habitat for some species. Specifically, farmed areas are often more hospitable if their structure mimics that of native vegetation (Fischer *et al.*, 2006). In ecosystems originally dominated by woody vegetation, structural similarity to native vegetation typically equates to structural complexity – structurally complex agricultural areas, generally speaking, thus are more beneficial for farmland biodiversity than structurally simplified areas.

There are many examples of this relationship. One of the best known ones is that of “shade coffee” plantations, especially when compared with “sun coffee” plantations (Rappole *et al.*, 2003). Shade coffee plantations that incorporate old native trees are structurally much more complex than sun coffee plantations, and a wide range of species can find suitable habitat in shade coffee (Box 2) (Figures 3 and 4). Arecanut plantings in India (and possibly other parts of Asia), too, can harbor a surprisingly rich bird fauna, partly because they are structurally similar to native forest patches (Ranganathan *et al.*, 2008). A similar situation also exists for reptiles in Australian farming landscapes. Provided the presence of native tussock grasses, fallen branches, and patches of leaf litter, a wide range of reptile species can use areas that are grazed by livestock (Fischer *et al.*, 2005).

Notably, not all elements of structural complexity are equally important. Some elements are disproportionately important relative to their size or footprint in the landscape. Examples of such “keystone structures” are ephemeral water bodies in north-eastern German fields (Tews *et al.*, 2004), or tree hollows in Australian forests (Gibbons and Lindenmayer, 2002). Both are used by a large number of species, which fundamentally depend on the existence of these structures.

One increasingly well-known example of keystone structures in farming landscapes is that of scattered trees (Manning *et al.*, 2006). Such trees are common in agricultural landscapes around the world, including commercially grazed oak savannas in Oregon (DeMars *et al.*, 2010), wood pastures in Europe (Bergmeier *et al.*, 2010), and agricultural landscapes in

Figure 2 (a) The relationship between the frequency of visits by wild insects to almond flowers in California orchards (mean per orchard $\pm$ SE) and the amount of surrounding natural habitat. The amount of surrounding natural habitat at a 1-km radius was classed as: low ($\leq 5\%$, $n=5$), low with a strip of seminatural vegetation ($n=5$), and high ($> 30\%$, $n=5$). Observations in each orchard were undertaken on three separate days in 2008. (b) Non-*Apis* visitors to almond flowers included (from top to bottom): the blue orchard bee *Osmia lignaria*, sweat bees (family Halictidae), and bumble bees such as *Bombus vonesenskii*. Unpublished data and photos by Claire Brittain and Alexandra-Maria Klein.

Box 2 The value of structural complexity for biodiversity: The base of coffee plantations

Coffee is produced in tropical areas around the globe. It is grown either in monocultures exposed to full sun, or under a layer of shade trees, which can exhibit different levels of structural complexity. Moguel and Toledo (1999) described the different forms of structural complexity in coffee systems of Mexico (Figure 3). Similar structures can be found in other parts of the world such as South-East Asia (Klein *et al.*, 2002, Figure 4).

Many studies have highlighted the potential of complex shade coffee to provide habitat for a diversity of plants (Hylander and Nemomissa, 2008), arthropods (Nestel *et al.*, 1993; Perfecto and Snelling, 1995), amphibians (Pineda *et al.*, 2005), birds (Tejeda-Cruz and Sutherland, 2004), and mammals (Williams-Guillén *et al.*, 2006). In addition, shade coffee may also “soften” the landscape matrix as a whole (Perfecto and Vandermeer, 2002; Pineda *et al.*, 2005) and may play a buffering role for natural rainforests (Moguel and Toledo, 1999; Tejeda-Cruz and Sutherland, 2004). Producing coffee under a complex array of shade trees has become a widely applied conservation measure, and has led various organizations to develop “biodiversity-friendly,” “wildlife-friendly,” or “bird-friendly” production systems, some of which are independently certified (Rappole *et al.*, 2003; Rainforest Alliance, 2009).

Although complex shade coffee systems provide habitat to a relatively large number of species, rare forest specialists often cannot be conserved in such systems (Rappole, *et al.*, 2003; Guevara, 2005). Saving patches of native vegetation (“land sparing”; see main text) therefore is an important complementary strategy to enhance biodiversity in landscapes used for coffee production. Certification programs for biodiversity-friendly coffee recognize the unique value of natural tropical rainforests for rare species. For this reason, certification is only being granted for areas that were previously used more intensively (Greenberg, 2001; Sustainable Agriculture Network, 2009) – this avoids the conversion of natural rainforest to (supposedly biodiversity-friendly) coffee production. Such conversion is a real threat to rainforests in some poor countries (Tejeda-Cruz *et al.*, 2010). To counteract this threat, conservation initiatives need to understand the socioeconomic drivers of land use change, and need to monitor the actual land use changes and conservation outcomes. Biodiversity conservation in landscapes used for coffee production thus requires a mix of strategies, including measures to ensure biodiversity-friendly production methods, but also measures to protect remnant patches of natural rainforest.

the wheat-sheep belt of eastern Australia (Ozolins, *et al.*, 2001; Maron and Fitzsimons, 2007). Scattered trees are disproportionately important because the marginal contribution of a single, semi-isolated tree to local biodiversity is many times larger than that of a single tree which is part of a large patch. In Australia, Fischer *et al.* (2010) documented that in a given 2 ha area used for livestock grazing, bat activity was ten times higher near a single tree than in an area without trees; and ten times higher again when there was a small clump of three to five trees (Figure 5). After that, bat activity barely increased with the presence of additional trees – the first few trees thus were most important.

Minimizing Chemical Use

The potentially disastrous consequences for biodiversity of chemicals in the environment have long been known. Most famously, in the 1960s, Rachel Carson warned against the then widespread use of the pesticide dichlordiphenyltrichlorethan because of its far-reaching biological consequences throughout the food web (Carson, 1962). Since then, and partly triggered by Carson’s efforts, a range of restrictions have been placed on the use of chemicals in many jurisdictions. But still, both the use of inorganic fertilizers and pesticides has increased steadily since the 1960s. While this has contributed to increasing agricultural productivity, it poses a range of threats to biodiversity (Tilman *et al.*, 2002), especially in poor tropical countries where many agro-chemicals are used that are banned in other wealthier countries (Wanger *et al.*, 2010).

Many ecosystems around the world have been negatively affected by fertilizer application. A useful conceptual model of the effects of inorganic fertilizers on grassland systems was developed by McIntyre and Lavorel (2007). They recognized several different states in grassland systems, from species-rich native systems to species-poor fertilized (or even sown) pastures. For transitions between the various states, the two most important drivers recognized were livestock grazing pressure

and fertilizer use. Especially in systems that are naturally nutrient-poor, fertilizer application can be disastrous. For example, fertilizer application would permanently destroy traditional hay meadows in Romania (Akeroyd and Page, 2007), and fertilizer application is one of the main reasons why trees are no longer naturally regenerating over vast areas of Australia’s wheat-sheep belt (Fischer *et al.*, 2009).

The use of pesticides is similarly problematic, with global pesticide use predicted to further grow (Tilman *et al.*, 2002; Wanger *et al.*, 2010). The impact of pesticides on biodiversity can be difficult to tease apart from other factors associated with agricultural intensification. However, there is evidence of widespread negative impacts on biodiversity (Geiger *et al.*, 2010; Relyea, 2005; Pimentel, *et al.*, 1992). Nontarget impacts are of particular concern. Such impacts occur when species not targeted by a particular chemical are negatively affected. Nontarget impacts recently have been implied as part of the reason for widely documented bee declines (Potts *et al.*, 2010; Oldroyd, 2007). Organisms that live in agricultural landscapes, such as honey bees, can be exposed to many different pesticides over long periods (Frazier *et al.*, 2008; Chauzat and Faucon, 2007), with unknown cumulative and synergistic effects. To reduce the pressure on wildlife from pesticides, several management measures can be effective. Such measures range from conservation headlands where pesticides are reduced along the edge of the crop (Longley *et al.*, 1997), to field margins that are sown with seed mixes to provide resources for wildlife (such as nectar for bees; see Box 1). In addition, patches of native or seminatural vegetation including hedgerows can protect wildlife from pesticide exposure (Otto *et al.*, 2009).

Finally, not just fertilizer and pesticides, but also other chemicals associated with industrial farming can cause unforeseen environmental problems. A high-profile example involved several species of vultures (*Gyps* spp.) on the Indian subcontinent (Oaks *et al.*, 2004). Rapid population declines of vultures had been documented starting in the 1990s. In 2004, a link was reported between these population declines and a veterinary drug, namely the anti-inflammatory drug diclofenac.

Figure 3 Schematic representation of increasing structural complexity in coffee-growing systems. From top to bottom (a–e) structural complexity decreases with the transition from shaded polyculture to unshaded monoculture. Reproduced from Moguel P and Toledo VM (1999) Biodiversity conservation in traditional coffee systems of Mexico. *Conservation Biology* 13: 11–21, with permission from Wiley.

This readily available drug was widely used to treat domestic livestock. However, the primary food source of vultures in this area was dead domestic livestock. Residues of the drug in dead livestock were highly significantly correlated with renal failure in the vultures, suggesting that the drug was the likely cause of unintended ecological consequences throughout the food chain (Oaks *et al.*, 2004).

Given the varied negative and difficult to predict consequences of chemical use for biodiversity, it follows that (generally speaking) farming operations are more biodiversity-friendly if chemical use is minimized. This is strongly supported through a range of papers on organic farming, where chemical use is absent or severely restricted. Recent reviews consistently show that on-average biodiversity increases in organic farming systems when compared with conventional systems (Batáry *et al.*, 2011; Hole *et al.*, 2005; Bengtsson, *et al.*, 2005); with the benefits often depending on the surrounding landscape context (*see* Biodiversity-Friendly Farming at the Landscape Scale).

The Timing of Disturbance Events

In addition to the general principles of maintaining an appropriate structure and minimizing chemical use, some location-specific farming practices can also be beneficial for biodiversity. Such practices often revolve around the balance and timing between periods of disturbance and periods of rest for a particular parcel of land. Examples exist both for livestock grazing and crop production.

For livestock grazing, two variables are important: the average stocking rate and the degree to which livestock stay in one place or move around the landscape. The stocking rate is of obvious importance because a higher number of livestock per unit area means greater pressure on the ecosystem. Frequently observed ecological consequences of overly high stocking rates include an impoverished flora and insect fauna, soil compaction, patches of bare soil, and subsequent risk of soil erosion (Oliver *et al.*, 2005; Yates *et al.*, 2000; Greenwood and McKenzie, 2001). By contrast, the relationship between

Figure 4 (a) Structural complexity in a traditional forest polyculture with coffee in Central Sulawesi, Indonesia; (b) coffee harvest in a traditional coffee polyculture in Manabi, Ecuador; and (c) ripe coffee berries of the polyculture in Ecuador.

Figure 5 The calling activity of bats, as measured at 63 individual 2-ha sites in a livestock grazing landscape in eastern Australia. Solid lines show means ($\pm$ standard error; left vertical axis); dotted lines show mean marginal change per additional tree (right vertical axis). The figure shows that the first few trees were particularly important in attracting bats to an area, suggesting that scattered trees are “keystone structures” in this example. Reproduced from Fischer J, Stott J, and Law BS (2010) The disproportionate value of scattered trees. *Biological Conservation* 143: 1564–1567.

livestock movement and biodiversity is less well understood. Many traditional livestock grazing systems that have also maintained high biodiversity are characterized by substantial livestock movement. One example is traditional sheep grazing in Transylvania, Romania (Huband, 2007). A single shepherd typically is responsible for many dozen sheep, which are owned by many different villagers. The shepherd takes these sheep out into pastures surrounding the village and returns to the village only approximately once a week, before taking the sheep out again to a different set of pastures (Akeroyd, 2006). During their time in the pastures, the sheep are in constant

movement. Grazing intensity is thus very high during the time a flock of sheep is present at a given location – but the same location is unlikely to be grazed again for many days or weeks.

A combination of high intensity grazing with prolonged rest periods between grazing events is also at the heart of rotational grazing. Rotational grazing is practiced, for example, on some ranches (sometimes also called “farms”) in the US, Australia, and parts of southern Africa. Advocates of rotational grazing believe it fundamentally benefits ecosystems because of the long rest periods between grazing events. The rationale is that short bouts of intense disturbance leave an ecosystem less damaged in the long term than constant low-grade pressure (Savory and Butterfield, 1999). While this rationale is appealing, empirical evidence on demonstrable benefits of rotational grazing is more difficult to come by (Briske *et al.*, 2008). In southeastern Australia, Fischer *et al.* (2009) demonstrated that native tree regeneration was more likely under rotational grazing than under continuous grazing. However, many examples exist where rotational grazing has not lived up to its promise. For example, rotational grazing systems in Arizona (USA) failed to maintain ground cover in drought conditions, with negative consequences for grassland birds (Bock and Bock, 1999). The usefulness of this practice therefore appears to depend on the location where it is practiced, and on the specific details of its implementation.

For cropping systems, too, the timing of management actions is important. In some parts of the tropics, agricultural systems are shifting toward shorter fallow periods (Dalle and De Bois, 2006), and European countries such as England have moved away from a mixture of spring and winter-sown crops in lowland agricultural land, toward a more simplified landscape of winter-sown cereals (Henderson *et al.*, 2009). These changes pose a potential threat to biodiversity because recovery time between disturbance events is reduced. Fallow periods associated with crop rotation can be beneficial for soil

microbial diversity (Lupwayi *et al.*, 1998), soil fertility, and natural pest management, thereby reducing the need for pesticides and fertilizers (Tilman *et al.*, 2002). For example, in North Carolina, Maize fields under 2- and 4-year rotations had significantly more pest predators and fewer corn root infestations than fields not in rotation (Brust and King, 1994). There is less information available on the impacts of different crop rotations on above-ground biodiversity. In Iowa, the richness of carabid beetles was higher in a 4-year (corn/soybean/triticale-alfalfa/alfalfa) crop rotation, than a 2-year (corn/soybean) crop rotation, most likely due to the inclusion of alfalfa (O'Rourke *et al.*, 2008). Similarly, in the UK, the populations of several species of birds increased over 5 years, following the introduction of a mixed rotation into a winter wheat system (Henderson *et al.*, 2009). While the general notion of crop rotation is beneficial for biodiversity in all of these examples, there are likely to be differential responses by various taxa, depending on the extent to which different species rely on particular resources and the timing of their life stages relative to crop management activities.

Maintaining Key Ecosystem Functions: Pollination and Pest Control

The processes of pollination and pest control are fundamentally important for biodiversity-friendly agricultural production. Conserving natural habitat, establishing conservation headlands, and sowing native flowers in field margins are all actions that can benefit pollinators on farmland (Box 1), along with reducing pesticide use or farming organically (*see* Minimizing Chemical Use). Maintaining and promoting pollination services in agricultural landscapes will require the conservation or establishment of resources necessary for populations of pollinators (Ricketts *et al.*, 2008). Such resources include food and nesting habitat (Box 1). Conserving and encouraging native pollinators can bring benefits to farmers by reducing dependence on a single species for pollination, namely the honey bee (*Apis mellifera*). In the watermelon, a crop whose production is largely dependent on pollination by bees, organic fields close to natural habitat received sufficient pollination services for fruit set just from wild bees (Kremen *et al.*, 2002). Moving away from reliance on a single species for pollination to a more diverse pollinator community is desirable as a safeguard against unforeseen environmental changes, especially in the context of widespread reductions in honey bee colonies (Potts *et al.*, 2010; Ellis *et al.*, 2010).

Biodiversity-friendly farming can also bring benefits through natural pest control. Organic farming (Letourneau and Goldstein, 2001) and noncrop habitat such as field margins (Bianchi *et al.*, 2006) can increase the number of predators for crop pests, thereby reducing the need for pesticide applications. Greater species evenness and natural pest control have been found in organic compared to conventional farms and in field enclosures where plant biomass was greater (Crowder *et al.*, 2010). Rotational and mixed cropping can also increase natural pest control on farms (Bianchi, *et al.*, 2006; Brust and King, 1994). Natural pest control may reduce the cost of pesticide applications for the individual farmer in the short term and may help to reduce the long-term costs of widespread pesticide

use (Pimentel, 2009). It also represents a more sustainable option in the long term, given the evolution of resistance of pests to commonly used pesticides (Brattsten *et al.*, 1986).

Criticisms of Biodiversity-Friendly Farming

Although many conservation biologists have passionately advocated biodiversity-friendly farming as a partial solution to the global biodiversity crisis, biodiversity-friendly farming has also been met with a range of criticisms. First, many governments have taken to the notion of biodiversity-friendly farming, and have established schemes that financially reward farmers for management actions that are deemed beneficial for biodiversity. However, reviews of the benefits of such schemes have found mixed results (Kleijn and Sutherland, 2003; Kleijn *et al.*, 2006; Knop *et al.*, 2006). Possible reasons for a lack of demonstrable benefits of some agri-environment schemes that support biodiversity-friendly practices include a lack of consideration of landscape context (Fahrig *et al.*, 2011; Whittingham, 2007) (*also see* Biodiversity-Friendly Farming at the Landscape Scale) and inadequate monitoring (Kleijn and Sutherland, 2003).

Second, some elements of biodiversity may be worth having on a farm from a conservation perspective, but in fact may cause substantial harm to crops. While the rhetoric of biodiversity-friendly farming is rife, in some ecosystems and for some crops, there are very real limits to the reality of its implementation. Monitoring programs typically consider only the positive aspects of biodiversity-friendly farming schemes, but do not consider disservices related to reduced productivity or higher production costs, resulting, for example, from wildlife destroying part of the harvest or acting as vectors for pathogen infections (Zhang *et al.*, 2007; Dunn, 2010).

Third, some conservation biologists have claimed that an exclusive focus on biodiversity-friendly farming is overly simplistic, and quite possibly detrimental to biodiversity conservation in some situations. Probably the most influential paper on this subject was published by Green *et al.* (2005). The main argument presented by these authors was based on the premise that biodiversity-friendly farming, because it is less intensive, typically results in lower yields per unit area. To meet the same demand for food, it then follows that a greater area is needed for biodiversity-friendly agriculture as opposed to intensive agriculture (*see also* Balmford *et al.*, 2005). Green *et al.* (2005) argued that in a scenario of intensive agriculture, the land not used for agriculture could be "spared" for nature. Depending on the response of biodiversity to increasingly intensive land uses, it is then possible that a series of relatively small areas "spared" from agriculture could support a greater diversity of species than vast areas of biodiversity-friendly farmland which incorporate no protected areas (Balmford, *et al.*, 2005; Green *et al.*, 2005).

The fundamental point of this argument is important – biodiversity-friendly farming must not be seen as a panacea for the problem of biodiversity decline in all ecosystems (Mattison and Norris, 2005). But there are many subtleties that suggest reality is in fact more complicated than a simple choice between "biodiversity-friendly farming" and "land sparing." Perhaps the most important criticism of the "land sparing" model is that some farming systems can produce

relatively high yields, while also being more biodiversity-friendly than industrial alternatives (Badgley *et al.*, 2007). Moreover, from the perspective of an individual farmer, high yields are not necessarily important to make a living. Some Australian cattle farmers, for example, have reported that biodiversity-friendly low-input systems have become increasingly attractive because input costs have risen – while these farmers now stock fewer cattle than in the past, their profits have in fact remained stable (J. Fischer, pers. obs.).

Intensive agriculture, typically assumed to be an unavoidable part of the notion of “sparing land” for nature, also involves a range of additional problems. Most importantly, the negative environmental effects of intensive agriculture are not constrained to the actual location that is being farmed. Rather, there is a range of “externalities,” that is, negative and often diffuse environmental consequences that occur elsewhere and are not easily accounted for. Such externalities include nutrient runoff into water bodies (Olsson *et al.*, 2008) and chemical drift into nearby areas (Duncan *et al.*, 2008), but also less tangible contributions to global environmental degradation, for example, through carbon emissions resulting from intensive land use (e.g., Garnett, 2009).

In addition, the notion that some land can be used intensively but other land “spared” within the same region may be unrealistic. Typically, intensive land use in a given area attracts even more intensive land-use to that area (Fearnside, 2002; Matson and Vitousek, 2006). Intensification thus often begets more intensification, rather than encouraging the preservation of land for nature.

Many variables influence the extent to which an area is suitable for intensive agriculture. Less intensive, biodiversity-friendly farming is most easily implemented in areas that have low productivity or steep topography, are heterogeneous and divided into small parcels of land, and occur near markets for environmentally benign (e.g., organic) food (Fischer *et al.*, 2008). In reality, biodiversity-friendly farming and intensive farming with areas “spared” for nature are therefore not truly opposed options. Rather, they occur on a continuum of levels of intensity and spatial use of the environment, and their adoption is influenced by a range of variables (Figure 6,

Fischer *et al.*, 2008). Because the world is a heterogeneous place, it is likely that there are some places where indeed, intensive agriculture might be preferable (Fischer *et al.*, 2009). However, in many areas, more biodiversity-friendly farming is possible – sometimes even without a loss in productivity (Stinner *et al.*, 1997). Notably, discussions about land sparing versus biodiversity-friendly farming are ongoing (Phalan *et al.*, 2011), and as yet, no broad consensus has been reached.

Biodiversity-Friendly Farming at the Landscape-Scale

Local decisions about how to farm have regional effects, and vice versa. This is true not only in a socioeconomic sense (e.g., intensification often begets more intensification; *see Criticisms of Biodiversity-Friendly Farming*), but also in an ecological sense (e.g., through either negative or positive neighborhood effects). On this basis, ecologists are increasingly interested not only in the local effects of different types of farmland on biodiversity, but also in the effects of entire farmland mosaics. Two landscape properties are particularly interesting in this context: heterogeneity and connectivity.

Landscape Heterogeneity

An increasingly consistent theme emerging from studies on biodiversity-friendly farming is that, other things being equal, heterogeneous farming landscapes support more biodiversity than homogenous farming landscapes (Daily *et al.*, 2003; Benton *et al.*, 2003; Haslem and Bennett, 2008). Policies aiming to promote landscape heterogeneity therefore can benefit the biodiversity of farming landscapes.

In addition, heterogeneity at the landscape scale can influence species richness at the local scale (Weibull *et al.*, 2003; Clough *et al.*, 2005). Local variables and landscape variables can interact, and it is their combination that shapes biodiversity at any given point in a farming landscape. In an influential paper, Tscharntke *et al.* (2005) proposed a general hypothesis of how the local effect of farming practices might depend on landscape context. Based on preliminary evidence,

Figure 6 Wildlife-friendly farming (or biodiversity-friendly farming) and land sparing occur on a continuum. A finer spatial grain in land use tends to be correlated with more biodiversity-friendly practices. Many underlying scientific traditions influence whether in a given situation, land sparing or wildlife-friendly farming are considered preferable. Reproduced from Fischer J, Brosi B, Daily GC, *et al.* (2008) Should agricultural policies encourage land sparing or wildlife-friendly farming? *Frontiers in Ecology and the Environment* 6: 380–385, with permission from ESA.

they proposed that complex or heterogeneous landscapes supported high biodiversity across the landscape. But further, they suggested that although such landscapes are important for biodiversity conservation, local measures to further enhance biodiversity in specific locations were likely to be relatively ineffective in heterogeneous landscapes. By contrast, in simplified or homogenous landscapes, total biodiversity is likely to be a lot lower, but partly for this reason, local measures to enhance biodiversity at specific locations might be more effective in such landscapes.

Evidence in support of this conceptual model is increasing. For example, in Sweden, local organic management only increased species richness and abundance in field margins in homogeneous, rather than heterogeneous landscapes (Rundlöf and Smith, 2006; Rundlöf, *et al.*, 2008). Similarly, in Germany, bee diversity was consistently greater in organic than conventional wheat fields, but the difference in diversity between paired organic and conventional sites was greater in a homogeneous landscape context than in a heterogeneous context (Holzschuh *et al.*, 2007). Most recently, Batáry *et al.* (2011) undertook a meta-analysis of the local effects of organic farming on a range of taxonomic groups in both homogenous and heterogeneous landscapes. While they found partial evidence in support of the original proposition, the model did not universally hold across all taxonomic groups or types of farming systems. On this basis, evidence is strong that landscape heterogeneity increases biodiversity at both local and landscape scales; and it appears that often (but not always) the effectiveness of local management actions is contingent on the landscape context.

Landscape Connectivity

Connectivity is likely to enhance biodiversity in farming landscapes. Structural links between similar patches of vegetation (i.e., “structural connectivity”) can help to facilitate the movements of individuals throughout the landscape (thereby providing “functional connectivity”) (Uezu *et al.*, 2005). Such connectivity is important to enable the movements of individuals on a daily basis (e.g., foraging movements; Saunders, 1980), to facilitate the exchange of individuals between subpopulations on an occasional basis (Hanski and Simberloff, 1997), and to facilitate gradual, large-scale movements of species (e.g., poleward or upward migration of species in response to climate change; Hickling *et al.*, 2006; Parmesan, 2006).

Connectivity in farming landscapes can be maintained via three complementary mechanisms. The first is managing the actual farmland matrix in a way that enhances its use by species (*see* Maintaining Structural Complexity in Farmed Areas). For example, Gascon and Lovejoy (1998) assessed the connectivity of cleared areas in the Amazon. They likened these areas to a filter – some species could move through cleared areas, whereas others could not. In this case, the “pore size” of the filter was partly determined by its vegetation structure, with more forest-like structure more likely to be used by forest birds. More generally, compared to a given species’ core habitat, a structurally similar matrix is more likely to facilitate the movement of this species than a structurally dissimilar matrix (Donald and Evans, 2006; Fischer, *et al.*, 2006).

The second mechanism that can enhance connectivity is that of stepping stones. At the landscape scale, the best known example of such stepping stones is that of scattered trees and the connectivity they provide for birds (*see* Maintaining Structural Complexity in Farmed Areas). For example, in Mexico, Guevara and Laborde (1993) demonstrated that frugivorous birds preferentially moved through the landscape via areas where trees were scattered relatively densely. A similar effect was documented for woodland birds in Australia (Fischer and Lindenmayer, 2002), and radio-tracking studies in Costa Rica also have reported positive effects of scattered trees on connectivity (Sekercioglu *et al.*, 2007; Gillies and St. Clair, 2010).

Finally, the most widely known method to enhance connectivity is that of corridors. In agricultural landscapes, such corridors can be traditional hedgerows (Wegner and Merriam, 1979), live fences (Harvey *et al.*, 2005), or linear restoration plantings (Lindenmayer *et al.*, 2010). As with all other kinds of structural connectivity, the mere presence of a structural link does not guarantee that the target species will actually move through a given corridor. Many factors influence whether a corridor is actually used, including a given species’ biology, the presence of predators, and the physical characteristics of the corridor (Lindenmayer and Fischer, 2006).

Conclusion

Biodiversity-friendly farming can be enhanced through a series of local management measures, which relate to the retention of native vegetation, the maintenance of structural complexity, the avoidance of chemicals, and the use of regionally-proven beneficial farming methods (many of which are related to the balance between disturbance events and periods of rest). In addition, local farmland biodiversity is influenced by its landscape context. Other things being equal, heterogeneous, or complex farmland mosaics support greater biodiversity than homogenous or simplified farming landscapes. Biodiversity-friendly farming thus is enhanced by maintaining native vegetation, encouraging heterogeneity and structural complexity, and avoiding the use of chemicals. While industrial farming may be appropriate in some situations, biodiversity-friendly farming offers opportunities for biodiversity conservation in many parts of the world.

This article is a revision of the previous edition article by David R. Notter, volume 1, pp 533–545, © 2001, Elsevier Inc.

Glossary

Breed “Either a subspecific group of domestic livestock with definable and identifiable external characteristics that enable it to be separated by visual appraisal from other similarly defined groups within the same species or a group for which geographical and/or cultural separation from phenotypically similar groups has led to acceptance of its separate identity” (FAO, 1999).

Breeding line Any distinctive livestock population. The term may be synonymous with “breed” but is also often applied to somewhat distinct subpopulations within a breed or to breeding populations, either purebred or crossbred, that are of fairly recent origin. Breeding lines may exist within a breed, and newly created lines may become recognized breeds.

Conservation Generally defined as the planned management of a natural resource to prevent exploitation, destruction, or neglect. Here, further specified as applying to livestock genetic resources and encompassing both *in situ* and *ex situ* maintenance of livestock genetic resources as well as the wise use and active development of those resources in structured breeding programs to meet appropriate development objectives.

Crossbreeding/crossbred Crossbreeding is the mating of animals of different breeds to produce commercial market animals or breeding animals. The resulting crossbred animals often exhibit improved fitness and performance compared to their purebred parents.

Cryopreservation Long-term storage of gametes, embryos, or somatic cells in liquid nitrogen.

Ex situ conservation Maintenance of a breed outside the environment and agricultural production system(s) in which it was developed and used. *Ex situ* conservation often involves cryopreserved gametes and/or embryos but may also involve live animals.

Genome The hereditary information contained in the DNA of eukaryotic organisms, including both genes and noncoding sequences of the DNA.

Germplasm Sources of hereditary material. In animal breeding the term is commonly applied to breeding animals and to fresh or frozen sperm cells, ova, and embryos.

In situ conservation Maintenance of a breed in the environment and agricultural production system(s) in which it was developed and used.

Phenotype The observed characteristics of an individual, such as the color, milk production, body weight, etc. The phenotype is a reflection of both the genome and its interactions with the environment during development.

Purebred An animal that is a member of a recognized livestock breed. Breed membership may be determined by pedigree records, geographical location, or knowledge of the breeding structure of the herd or flock. Animals that possess the full range of characteristics commonly associated with a specific breed are sometimes also designated as purebreds, but the designation must be recognized as subjective in these cases.

Introduction

Domestic animals make crucial contributions to human well-being as sources of food, fiber, power, and many other products and services. Worldwide, domestic animal production centers on a small number of globally distributed species, including cattle, pig, sheep, goat, horse, donkey, rabbit, chicken, duck, goose, and turkey. These are augmented by a similar array of regionally important food- and fiber-producing species, such as water buffalo, dromedary and Bactrian camel, llama, alpaca, yak, reindeer, and guinea pig. Species-level domestic animal biodiversity is thus very limited, representing *in toto* approximately 20 completely domesticated, and perhaps an additional 25 partially domesticated, species. Genetic diversity within domestic species, however, is vast especially for the globally distributed species. Domestic animal genetic diversity evolved in synchrony with human dispersal as domestic animals accompanied their owners from their centers of domestication

to every corner of the globe. Importantly, humans also provided these animals with the marginal levels of care, shelter, protection, and supplemental food that facilitated their adaptation to the diverse environments that they encountered. The resulting environmental adaptations, coupled with selection to meet a variety of human needs and preferences, resulted in the creation of an incredibly rich domestic animal fauna.

In the past three to four decades, an increasingly intense process of industrialization and concentration of production has occurred, particularly in egg- and meat-producing chickens and, to a smaller extent, in pork and milk production (Gura, 2008; FAO, 2010c). As a consequence, substantial erosion of between- and within-breed genetic diversity has occurred, not only in developed countries but also increasingly in developing countries (FAO, 2010b). Thus the potential of humankind to adapt production to changing demands and climate increasingly relies on a declining pool of farm animal genetic diversity.

Overview of Livestock Genetic Diversity

Breeds of Livestock

Populations of domestic livestock are traditionally subdivided and isolated from other subpopulations by both distance and controlled breeding. These subpopulations are generally known as “breeds.” A single, widely accepted definition of a livestock breed does not exist, but livestock breeds are approximately analogous to the subspecies or races of wild species. Thus, the Food and Agriculture Organization of the United Nations (FAO) defines a livestock breed as:

Either a subspecific group of domestic livestock with definable and identifiable external characteristics that enable it to be separated by visual appraisal from other similarly defined groups within the same species or a group for which geographical and/or cultural separation from phenotypically similar groups has led to acceptance of its separate identity (FAO, 1999).

The concept of a livestock breed arose in nineteenth-century England, where influential livestock breeders, including the noted Robert Bakewell, began to improve the native livestock of the region by controlled mating and selection of presumed superior individuals. Significantly, their activities included the establishment of “herd books” for most mammalian breeds which enumerated the pedigrees of animals within each breed so that breed membership was confirmed by records of ancestral ties to presumed elite foundation animals. These so-called “purebred” livestock thus had pedigree documentation of breed identity. Similar activities in poultry resulted in establishment of many avian breeds, although individual pedigree recording was not usually practiced for these smaller, more prolific species. This breed concept became widespread in Western Europe and in areas that were settled or influenced by Western Europeans. By the early twentieth century, a central part of livestock breeding in these areas was the identification and use of distinct, ostensibly superior, genetic types and the establishment of breeds to propagate these types.

The Western European definition of a breed had little meaning in most of Asia and Africa, where extensive pedigree recording does not appear to have arisen. However, selective breeding certainly did occur in these areas, and regionally distinct livestock types arose and were propagated. Isolation of these types was generally by distance or selective matings based on adaptation to local environmental conditions or obvious phenotypic traits such as color or horn shape rather than on pedigree information. However, pedigree information was occasionally accorded great value, as in the establishment of the Arabian horse. Today, the term breed has become globally pervasive and is used to describe any identifiable subpopulation possessing relatively distinct characteristics and maintained with a reasonable level of reproductive isolation.

Genetic Structure of Livestock Populations

Livestock breeds represent a partitioning of the genetic diversity within each species. Through many generations of

selection and relative reproductive isolation, each of these subpopulations has become a distinctive genetic entity possessing specific combinations of genes and associated phenotypic characteristics. The core value of these breeds lies in the reliable access they provide to these combinations of genetically defined characteristics. For example, ewes of the prolific Russian Romanov sheep breed are capable of producing three to six lambs at a time. Sheep breeders interested in improving prolificacy can thus rely on this breed as a source of useful genes.

The traditional (i.e., mid-twentieth century) genetic structure of most livestock species was thus characterized by many regionally isolated subpopulations. In addition, several distinct subpopulations could often be identified within each region, maintained in more or less pure form by breeders who favored animals of a specific type. These dual mechanisms for maintaining reproductive isolation fueled development of levels of observed genetic diversity that are generally far in excess of those observed in wild species.

It would be incorrect, however, to view the livestock breeds as fixed, immutable genetic entities. Migration, or the exchange of genetic material, among breeds is not uncommon. Even among breeds that maintain pedigree records, decisions to “open” the herd book occasionally occur to allow incorporation of desirable animals from outside the breed. Breeds wax and wane in popularity. Some breeds merge, others are absorbed by more popular breeds, and a few simply lose favor and gradually disappear. Breed evolution is thus an accepted part of livestock breeding. This traditional genetic structure of livestock breeds is remarkably similar to that proposed by Wright (1940) as optimal for evolution in natural populations, with relatively high levels of reproductive isolation, modest effective population sizes, diverse selection pressures, and levels of migration that provide for periodic infusions of genes without seriously compromising the genetic integrity of the subpopulations.

Livestock breeds in most cases possess very significant amounts of within-breed genetic diversity. Although breeds can rightly be viewed as mildly inbred lines, they do not approach the levels of genetic uniformity commonly found in plant breeding lines in which self-fertilization and clonal propagation can strongly limit, and in some cases completely eliminate, genetic diversity. Thus, essentially all livestock breeds retain significant evolutionary potential and can undergo significant genetic changes in response to selection, either natural or artificial. Livestock breeds retain the capacity to change, sometimes radically, in response to changes in breeders’ preferences or market demands without losing fundamental characteristics of the breed.

Finally, within each of the domestic species, a very large number of individuals exist that do not exhibit or possess unambiguous breed ancestry. Worldwide, many domestic animals commonly display apparent breed affinity, manifested by the color or morphology of recognized local breeds, but lack either the pedigree documentation or the full array of phenotypic characteristics necessary to confirm breed identity. For example, more than 90% of the dairy cows in the United States would be visually classified as Holsteins, but at most one-third of these would be recorded in herd books as purebred animals. The proportion of animals recorded in herd

books is much lower, rarely exceeding 10%, in cattle used for meat production, sheep, and goats.

Many other animals are obvious crossbreds, showing mixtures of specific breed characteristics that suggest a somewhat predictable breed ancestry. Also, large numbers of animals are often truly nondescript, exhibiting a collage of various breed characteristics that indicate a more diverse ancestry. The value of crossbred or nondescript animals as a genetic resource is hotly debated. Populations are often large and well adapted to prevailing environmental conditions. Although adapted local breeds are often viewed as “contaminated” by crossing with less well adapted, imported breeds, these populations also provide opportunity for creation of new genetic combinations and for selective elimination of undesirable breeds. Thus, these animals represent a potentially useful genetic resource but lack the predictability of the pure breeds for use in commercial livestock production.

Current Trends in Livestock Diversity

The most significant event in global genetic resource utilization in the late twentieth century was the development of highly productive livestock breeds which are now widely distributed globally. These breeds, for the most part, arose in the developed nations of the temperate zones and have had a remarkable impact on livestock production worldwide. They include the Holstein dairy cow, capable of producing up to 60 kg of milk per day for 300 days; the White Leghorn layer chicken, which can produce up to 325 eggs per year; the modern broiler chicken, which can reach a market weight of 2 kg in less than 35 days and on less than 3.5 kg of feed; and Merino sheep with wool fiber diameters of 13–15 μm .

The development and continued improvement of these global breeds is viewed in many quarters as the capstone of modern animal breeding. Large population sizes, detailed recording of performance, and intensive selection fueled their development. Well-organized breeders’ groups and, more recently, multinational corporations are involved in their propagation. If we extrapolate figures from Steinfeld *et al.* (2006) and assume that increases in production between the early 2000s and 2009 are exclusively attributable to expansion of industrial systems, then we conclude that industrial systems based on commercial breeding lines provide 79% of global poultry meat, 73% of eggs, and 63% of global pork production (Hoffmann, 2011). The emergence of corporate animal breeding, in particular, allowed merging of genetic improvement, production, processing, and marketing activities and provided resources for aggressive international marketing of germplasm. Within the developed nations, the global breeds have made an important contribution to maintain low food costs, but many of the traditional livestock breeds in these areas have declined because they cannot compete with these global breeds.

Because of their tremendous production potential, these highly developed global breeds also caught the attention of government planners and officials in developing nations. Their global dissemination was seen as a magic bullet to improve animal productivity, analogous to the improvement in crop yields associated with the Green Revolution. Widespread

importations of these breeds into developing nations had a negative impact on indigenous breeds, sometimes through outright breed replacement but more often through extensive and generally unregulated crossbreeding between imported and indigenous breeds (Box 1). In rural areas and subsistence production systems, the contributions of these highly productive global breeds were often disappointing. When denied the high levels of feeding, housing, and veterinary care under which they were developed and forced to grapple with unfamiliar levels of disease, low-nutrient feeds, and climatic stress, the highly productive global breeds and their crosses were often unable to forage, survive, and reproduce at acceptable levels and were ultimately less productive than the adapted indigenous types they were intended to replace.

Improved technology for transfer and use of genetic material contributed to the demise of many indigenous breeds. Use of frozen semen became commonplace in cattle in the latter half of the twentieth century and is now widespread for many livestock species. Use of frozen embryos is also widely practiced for cattle, sheep, and goats. These developments allowed efficient global exchange of genetic material and effectively ended the genetic isolation of many breeds, especially in Asia and Africa, where the concept of breed identity was less strong than in Europe and North America. Greater ease of transport of live animals also facilitated establishment of populations of foreign breeds and replacement or contamination of native breeds, especially for the smaller or more fecund species such as poultry and pigs. Thus, modern reproductive technologies today permit foreign breeds to have a much greater and more rapid impact, and in some cases to completely replace native breeds.

Urbanization and economic development have also opened important niches for use of global breeds in developing nations. Demand for animal products in these countries has soared in recent years and is expected to increase continuously, resulting in movement from subsistence production to market-driven production and changes in production systems. In particular, urbanization has concentrated animal production in periurban areas to allow convenient access to population centers and has led to opportunities for more intensive production. These changes have occurred despite concerns over economic disenfranchisement of farmers in rural areas, air and water pollution and waste disposal in periurban production, and the long-term sustainability of these production systems. Intensive animal production systems in periurban areas have also expanded the use of highly productive global breeds at the expense of adapted native types. The competitive advantage of these intensive periurban systems may decline however, once the full costs of waste disposal and environmental impacts are incorporated into production costs, and if costs of harvested feeds increase due to competition for land and crops for human food and biofuel, thereby providing justification for a return to more traditional mixed-farming systems and breeds.

Animal welfare concerns may also influence the use of livestock breeds. In Europe, concerns over issues of animal welfare in intensive production systems have prompted a return to less-intensive conditions and a corresponding need for animals that produce well under those conditions. Increased interest in consumption of locally produced foods, natural

Box 1 Crossbreeding: Threat or boon to animal genetic resources?

The production of crossbred animals by mating parents of different breeds is common in livestock breeding. Crossbred animals are often superior to their purebred parents and therefore more desirable for commercial farmers. The desirability of crossbred livestock arises from two sources: heterosis and complementarity.

Heterosis, also known as hybrid vigor, is normally manifested as an increase in fitness of crossbreds relative to their purebred parents. Thus, crossbred animals commonly are more fertile, more disease resistant, and better able to cope with environmental stresses than would be predicted from the average fitness of their purebred parents. As a result, productivity traits such as growth and milk or egg production are also usually improved in crossbred animals. In simple terms, purebred individuals commonly show modest levels of inbreeding as a result of the restricted matings required to genetically fix the defining characteristics of the breeds (e.g., colors and horn shape), and inbreeding commonly results in associated modest reductions in fitness. Crossing of purebred animals relieves accumulated inbreeding and provides an economically significant “kick” in performance. Significantly, however, effective use of hybrid vigor requires the crossing of unrelated parent breeds and is maximally expressed only in the first-generation cross. Thus, hybrid vigor can be maximally exploited and reliably captured only when parents of the original breeds are maintained as purebreds and mated in specific ways.

Complementarity is a characteristic of the production system which arises when different breeds play different and appropriate roles in crossbreeding systems. In low-input or extensive-production systems, adaptation of breeding females to the production environment is critical. If the environment is harsh, the productive capacity of indigenous breeds is often low, thereby allowing demands for nutrients and other inputs to be synchronized with their limited supply. In meat production, mating of females of indigenous breeds to males of more productive and heavily muscled breeds can increase the value of the offspring while maintaining high levels of adaptation in the breeding females. Additionally, the benefits of having a well-adapted mother and of hybrid vigor often permit the crossbred offspring to perform at acceptable levels and increase overall productivity. However, successful use of complementarity again requires maintenance of the adapted, indigenous breeds. Replacement of the original indigenous breeding females with crossbreds results in losses in both adaptation and hybrid vigor, often with serious negative effects on productivity.

Proper use of crossbreeding thus relies on breed diversity. Access to arrays of both adapted and highly productive breeds allows synchronization of the genetic characteristics of both breeding females and crossbred offspring to diverse production environments and markets. However, proper use of crossbreeding also requires that breeds be maintained in their proper roles in the system. In developing nations, in which control over matings is often limited or nonexistent, use of highly structured crossbreeding systems has proven difficult, and initial improvements in productivity in first-generation crosses, as well as the genetic integrity of the indigenous breeds, have been lost through indiscriminate mongrelization of adapted and unadapted breeds. Thus, crossbreeding has significant benefits when an appropriate management infrastructure exists but can have devastating effects on indigenous breeds when not adequately managed.

food products, and regionally or breed-based branded food products likewise has potential to create niche markets for traditional breeds. This phenomenon is most advanced in countries with relatively high disposable incomes, but premiums for locally produced poultry meat from traditional breeds are also becoming common in developing countries.

Conservation Planning: Coordinating the Use and Conservation of Livestock Genetic Resources

Animal breeders are often confronted by an apparent dilemma in the design of livestock breeding programs. On the one hand, maximizing livestock productivity relies on the identification and propagation of superior genetic types. Rates of genetic improvement are generally proportional to the intensity of selection. Thus, propagation of small numbers of elite parents yields greater rates of progress than retention of larger numbers of less-desirable individuals. Indeed, most of the accomplishments of modern animal breeding have resulted from improving the accuracy of genetic evaluation of prospective parents and increasing the number of offspring of these selected parents by use of artificial insemination (AI), embryo cloning and transfer, and other advanced reproductive technologies.

Successes of modern animal breeding programs have, in some cases, been spectacular, as exemplified by the emerging global breeds of poultry, swine, and dairy cattle. The global proliferation of industrial production systems has relied primarily on these species because of their greater efficiency of use of harvested feeds. In other species, such as the grazing ruminants, successes have been more modest, largely because these animals are generally produced under extensive conditions and required to interact closely with their environment to harvest forages, but still have been substantial. Despite these successes, demands for further increases in rates of animal production to supply an expanding human population continue to increase, and pressure to utilize the highly productive global breeds to meet these demands is tremendous.

Improvement-oriented animal breeders view global genetic diversity as a resource to be used in pursuit of improved animal productivity. The existing array of livestock breeds is recognized as potentially valuable but primarily as a consumable resource to be integrated into elite populations as appropriate and molded into ever-improving commercial populations. This viewpoint, described as the “utilizationist view” by the US National Academy of Sciences (NRC, 1993), emphasizes the potential value of the unique genes and gene combinations found in the various breeds as raw material for breed evolution and emphasizes the value in maximizing that evolution. In the utilizationist view, there may well be a need for a few dozen different pig breeds to meet the demands of different global production environments and markets, but a commitment to maintain all of the 656 currently recorded pig breeds (FAO, 2010b) would be seen as excessive and counterproductive.

In contrast to this position is a more “preservationist view” which tends to accord individual breeds a position similar to that of an endangered species and proposes similar management strategies to sustain them. The preservationist view emphasizes the unique history and presumed genetic distinctness of individual breeds and takes breed preservation *per se* as its goal. Blending of breeds to generate improved, adapted commercial populations is acknowledged to be necessary and desirable, but only against a backdrop of secure and relatively stable populations of the contributing breeds. Retention and continued use of existing breeds in their traditional

environments and production systems is promoted, even if public subsidies are required to ensure that use.

Synthesis and rectification of the utilizationist and preservationist views is badly needed but has yet to fully occur in the animal breeding community. The utilizationists have, to some extent, become victims of their successes, especially in poultry, dairy cattle, and pig production. Aggressive and widespread sampling and comparative evaluation of breeds in the mid-twentieth century led to the establishment of today's global breeds and to the replacement of many of the mid level, often dual-purpose, breeds that were widely represented in commercial production a few decades ago. Although large numbers of locally adapted, relatively low-productive breeds of poultry and swine still exist globally, the elite global breeds have become so differentiated from these stocks that there is now thought to be minimal opportunity for these breeds to contribute genetic material to the elite global breeds through traditional breeding methods. Thus, industrial stocks of chickens and turkeys have experienced no outside contributions from other breeds in more than 35 years. A similar situation exists for modern pig populations, and, in the temperate regions, the Holstein dairy cow is rapidly becoming the preeminent, and in many cases exclusive, dairy breed. Increasingly, the elite global breeds are viewed as dependent on existing reservoirs of within-breed genetic diversity for future adaptation and improvement. In contrast, the preservationist position has been made untenable by the events of global economic and social homogenization. In an increasingly cosmopolitan, interdependent, and rapidly changing world, continued use of nearly 7000 local livestock breeds (FAO, 2010b) will not occur and is not necessary to maintain adequate reservoirs of genetic diversity. However, a responsible fallback position which can ensure the identification, retention, and ready access to the core genetic diversity of each domestic species is badly needed.

A reasonable synthesis and integration of conservation and genetic improvement activities have been achieved in the plant breeding community, as described elsewhere in this encyclopedia. Facilities for long-term seed storage exist and have both a broad mandate and the budgetary support to acquire and preserve samples representing the full range of diversity within individual species of crop plants and their wild relatives. The importance of these programs is acknowledged by both public agencies and private breeding companies. Even though there are fundamental differences between plants and animals in the population structure of breeding materials, technologies that can be used for genetic resource conservation, and use of wild relatives in commercial breeding (Box 2), a more assertive and proactive approach to animal germplasm conservation is still needed.

Management Strategies for Sustainable Use and Conservation of Livestock Genetic Resources

Leadership in global management of conservation of livestock genetic resources has come from the FAO, beginning with many *Animal Production and Health Papers* (http://www.fao.org/ag/againfo/resources/en/pubs_gen.html), continuing with the *Global Strategy for the Management of Farm*

Box 2 Use of wild relatives in livestock breeding

In contrast to plants, use of wild relatives as a source of genetic material for industry breeding programs in livestock is limited. In most cases, domestic animals represent distinctive species and wild progenitors of these species are no longer found. However, several recent developments suggest that wild relatives may be an useful source of genetic material and that the pool of useful wild relatives may be broader than originally thought.

In bovines, hybrids of domestic cattle with gaur (*Bos gaurus*), banteng (*B. javanicus*), and yak (*B. mutus*) are common in Asia and make important contributions to livestock production. In North America, hybrids of cattle and bison (*Bison bison*) were evaluated in Canada in the 1960s but with limited success because of near-complete infertility of hybrid males. Crosses of bison and cattle in the United States, however, yielded enough fertile hybrid males to allow establishment of herds of animals, known as beefalo, possessing a mixture of genes from cattle and bison. These animals were claimed to possess some desirable adaptational and meat quality traits but are today primarily a novelty.

In western China, genes from the wild ibex (*Capra ibex*) were introduced into domestic cashmere goats. The yield of cashmere from ibex is very low, but the cashmere fibers are very fine, averaging approximately 12 μm in diameter. Typical cashmere goat fibers are 16 or 17 μm in diameter, and the value of the fiber is related to its fineness. Introgression of genetic material from ibex, followed by selection for yield and fineness of cashmere, led to development of animals with 12.5–25% ibex genes that possess increased fineness of the cashmere with near-normal yield. Similar crossing programs have been proposed using the wild vicuña to improve fiber quality in domestic alpaca.

In the Republic of South Africa, there is a need for hardy and well-adapted livestock for use in communal and other low-input production systems. In pigs, crosses between an endangered domestic pig breed, the Kolbroek, and the wild bush pig (*Potamochoerus porcus*) led to production of fertile offspring with improved hardiness, foraging ability, and capacity to digest fiber. This inter-generic cross also indicates the potential to use more distant crosses as a source of genetic material.

Wild relatives of domestic livestock have also contributed to development of genetic maps. Crosses of domestic pig with wild boar (*Sus scrofa*) were used to develop gene maps for pig, and crosses with red junglefowl (*Gallus gallus*) were used in mapping the chicken genome.

In plant breeding, wild relatives of domestic crop plants have long been recognized as a source of genes for disease and pest resistance. Studies involving wild relatives of tomato and rice suggest similar opportunities to improve production traits. Use of gene maps to identify useful genetic material and of improved methods to introduce this material into domestic stocks using either biotechnology or conventional breeding methods now exist for plants and will be developed for animals.

Animal Genetic Resources (FAO, 1999), and recently culminating in the *State of the World's Animal Genetic Resources* (FAO, 2007a) and the *Global Plan of Action for Animal Genetic Resources* (FAO, 2007b). FAO also leads the program of the Convention on Biological Diversity on agricultural biodiversity (CBD, 2006, 2008a, b). The Domestic Animal Diversity Information System (DAD-IS; <http://www.fao.org/dad-is>) is a comprehensive multilingual web-based clearing-house mechanism for animal genetic resources and is being further developed by FAO to allow modeling of the impacts of climate change on breeds of livestock. The 2007 *State of the World's Animal Genetic Resources for Food and Agriculture* was the first comprehensive global assessment of the roles, values, status, and trends of animal genetic resources; the capacity at both country and international levels to manage these resources; and the state of the art in management of animal

genetic resources (Hoffmann *et al.*, 2011). The report was the result of a country-driven process based on 169 country reports (<ftp://ftp.fao.org/docrep/fao/010/a1250e/annexes/CountryReports/CountryReports.pdf>), nine reports from international organizations, scientific literature and FAO's DAD-IS, and statistical databases. The State of the World report was launched at an international conference at Interlaken, Switzerland, in September 2007. At this conference, governments agreed on the *Global Plan of Action for Animal Genetic Resources*, the first-ever international framework for the promotion of the wise management of animal genetic resources for food and agriculture, and the Interlaken Declaration. Both were later endorsed by the 191 member nations of the FAO.

The Global Plan of Action (Box 3) contains 23 Strategic Priorities for Action, clustered into four priority areas covering all areas of management of farm animal genetic resources:

1. Characterization, inventory, and monitoring of trends and associated risks;
2. Sustainable use and development;
3. Conservation; and
4. Policies, institutions, and capacity-building.

The main responsibility for implementation of the Global Plan rests with national governments. However, governments (and especially governments of developing countries) are supported by the international community, including FAO, bilateral and multilateral donors, and international research and development institutions.

Inventory, Description, Characterization, and Assessment of Degree of Endangerment

Understanding the status and trends of domestic animal genetic diversity is prerequisite to its successful management, and the inventory, description, and comparative characterization of livestock breeds is a key management activity. Part 1 of *The State of the World's Animal Genetic Resources* (FAO, 2007a) describes the state of livestock biodiversity with annexes listing breeds categorized in different risk statuses (see <http://www.fao.org/docrep/010/a1250e/a1250e00.htm>). Two additional status and trend reports have also been prepared and published (FAO, 2009b, 2010b).

The 2010 status and trend report catalogs 8054 breeds, including 5833 mammalian and 2221 avian breeds representing 37 species used for food and agriculture and reported by 182 countries (Figure 1). Of these, 631 breeds are classified as extinct and are not included in Figure 1. More than 1000 breeds are represented in more than one country, and the total number of country-level breed populations is 10,507 for mammals and 3414 for birds. However, data on population size and status are available for only 54% of mammalian and 47% of avian breeds. The remaining breeds have only cursory information on breed characteristics and distribution. Reporting of breed information is likewise not consistent throughout the world. European breeds dominate the list, with 4127 mammalian and 1609 avian entries, primarily because Europe was the cradle for the concept of breed formation and because of a long history of concern over genetic diversity. African breeds, in contrast, are almost certainly

Box 3 FAO's Role in Implementing the Global Plan of Action

FAO, in partnership with governments, international organizations, research organizations, and nongovernmental organizations, facilitates global and regional collaboration and networks; supports the convening of inter-governmental and technical meetings; maintains and further develops the Domestic Animal Diversity Information System (DAD-IS); develops communication products; provides technical guidelines and assistance; coordinates capacity-building and training programs; and promotes the transfer of technologies related to sustainable use, development, and conservation of AnGR. Guidelines to assist countries in the implementation of the Global Plan of Action are being developed, including:

- preparation of national strategies and action plans for animal genetic resources (FAO, 2009a); and
- breeding strategies for sustainable management of animal genetic resources (FAO, 2010a).

Further guidelines are under development and will complete the set and provide guidance to policy makers as well as technicians comprehensively in all four priority areas. These include:

- Development of the institutional framework for the management of animal genetic resources (<http://www.fao.org/docrep/meeting/021/am137e.pdf>).
- Surveying and monitoring (<http://www.fao.org/docrep/meeting/021/am133e.pdf>).
- Phenotypic characterization (<http://www.fao.org/docrep/meeting/021/am134e.pdf>).
- Molecular genetic characterization (<http://www.fao.org/docrep/meeting/021/am135e.pdf>).
- Cryoconservation (<http://www.fao.org/docrep/meeting/021/am136e.pdf>).

Guidelines on animal identification and recording and *in situ* conservation are being developed, and individual countries are developing national strategies and action plans (Hoffmann and Scherf, 2010). In celebration of the International Year of Biodiversity 2010, FAO produced a special issue of its journal *Animal Genetic Resources* (<http://journals.cambridge.org/action/displayJournal?jid=AGR>) focusing on the four priority areas of the Global Plan and invited national coordinators for the Management of Animal Genetic Resources (<http://dad.fao.org/cgi-bin/Efa-bisWeb.cgi?sid=-1,contacts>) and international organizations to prepare posters describing implementation of the Global Plan (<http://www.fao.org/ag/againfo/programmes/en/genetics/natcord.html>). Most of the FAO documents referenced in this article can be accessed via the DAD-IS library (<http://dad.fao.org/>) or the AGA homepage at http://www.fao.org/ag/againfo/resources/en/pubs_gen.html.

underreported, with only 1669 mammalian and 421 avian breed populations listed.

To be useful, inventory information must be augmented with some objective assessment of degree of endangerment of the populations involved. The current FAO system for determining breeds at risk is shown in Table 1 (<ftp://ftp.fao.org/docrep/fao/010/a1250e/a1250e.pdf>). Based on this classification, approximately 18% of mammalian and 31% of avian breeds with population data are considered to be at risk (Figure 2). More detailed risk-status assessments are shown by species for mammalian and avian breeds in Figures 3 and 4, respectively. Furthermore, only 19% of mammalian breeds and 21% of avian breeds that are at risk have active programs in place to promote their conservation. Because many of these endangered breeds are found in harsh production

Figure 1 Numbers of local and transboundary breeds at global level (excluding extinct breeds).

Table 1 FAO risk status classification

Category	Criteria
Not at risk	Total number of breeding females is greater than 1000 and total number of breeding males is greater than 20; or population size approaches 1000, the percentage of females being bred to males of the same breed is near 100%, and the overall population size is increasing.
Endangered	Total number of breeding females is greater than 100 and less than or equal to 1000 or the total number of breeding males is less than or equal to 20 and greater than five; or the overall population size is greater than 80 and less than 100 and increasing and the percentage of females being bred to males of the same breed is above 80%; or the overall population size is greater than 1000 and less than or equal to 1200 and decreasing and the percentage of females being bred to males of the same breed is below 80%, and it is not assigned to any of above categories.
Endangered-maintained	Endangered populations for which active conservation programs are in place or populations are maintained by commercial companies or research institutions.
Critical	Total number of breeding females is less than or equal to 100 or the total number of breeding males is less than or equal to five; or the overall population size is less than or equal to 120 and decreasing and the percentage of females being bred to males of the same breed is below 80%, and it is not classified as extinct.
Critical-maintained	Critical populations for which active conservation programs are in place or populations are maintained by commercial companies or research institutions.
Extinct	No breeding males or breeding females remaining. Nevertheless, genetic material might have been cryoconserved which would allow recreation of the breed. In reality, extinction may be realized well before the loss of the last animal or genetic material.
Unknown	Information on population size is not available.
Breed at risk	A breed that has been classified as critical, critical-maintained, endangered, or endangered-maintained.

environments with minimal external inputs and management, they can reasonably be anticipated to possess unique genetic adaptations and disease-resistance characteristics. However, in common with many endangered species, they are at risk of disappearing before they can be adequately evaluated and characterized.

Conservation Strategies

Conservation of livestock genetic resources will almost certainly involve both *in situ* conservation of breeding herds in agricultural production systems and *ex situ* conservation of animals, gametes, embryos, and somatic cells in reserves and cryogenic repositories. Issues of current utility, degree of endangerment, and cost of conservation will determine the method(s) of choice.

In Situ Strategies

Strategies that are based on effective use of livestock genetic diversity in commercial and/or subsistence production systems are most likely to provide the security necessary to allow breeds to remain viable and maintain the population sizes necessary to ensure continued improvement. Thus, a key activity in livestock genetic resource conservation is the comprehensive appraisal of the productive merit of the various breeds under current and anticipated future production conditions.

Most of the world's domestic animals are found in developing countries, and nearly two billion people obtain at least a part of their livelihood from livestock. Rapid changes in production conditions have occurred in some of these countries, but the number of animals used in subsistence production systems remains very large. Levels of veterinary care,

Figure 2 Proportion of the world's breeds at risk by status risk status category.

supplemental feeding, and shelter from climatic stresses are often limited, and adaptational characteristics of indigenous livestock remain important to many farmers. Studies throughout the world have confirmed that if environmental conditions are harsh, imported temperate breeds of high-production potential often experience increased levels of mortality and morbidity and reduced reproductive success, and therefore may be less productive per unit of time or per unit of inputs than indigenous breeds. Advisors often recommend changes in the production environment, even though farmers commonly do not have the financial resources or market incentives to do so. A more responsible strategy, and one that is more consistent with conservation of livestock diversity, is to focus on retention and improvement of local breeds (Madalena, 2008). The implementation of modern livestock improvement procedures in indigenous breeds can allow them to be improved in parallel with gradual improvements in production conditions while retaining important adaptational characteristics.

An example of such an approach is found in India, where Operation Flood was begun more than 40 years ago to enhance milk production and marketing opportunities for smallholders in western India. The goal was to improve the nutrition of the people of India by increasing supplies of

buffalo and cattle milk. Certainly, Operation Flood and its successor projects have been a quantitative success. India is now the world's number one producer of milk. Much of this success was achieved without recourse to establishment of high-volume Western dairy production systems or a rapid infusion of poorly adapted foreign germplasm. Instead, emphasis was placed on establishing marketing conditions that would reward efficient producers and provide incentives for improved production practices. Only in the past decade has the identification of superior germplasm within indigenous breeds of cattle and buffalo and strategic use of imported breeds become a part of this program. In Latin America, Brazil has likewise been a leader in the utilization of adapted temperate and more recently introduced tropical genetic resources to create highly productive, optimally adapted populations of dairy cattle (Madalena *et al.*, 1990).

In other cases, however, the pace of socioeconomic change has been so rapid that indigenous breeds in the developing nations cannot meet the challenges. Under these conditions, pressures on indigenous breeds can become extreme very quickly, and careful analysis is required to identify appropriate genetic resource development activities. Developments in pig production in China provide an example. China has the world's most diverse array of pig breeds, with 142 reported

Figure 3 Risk status of the world's mammalian breeds by species in October 2010 in terms of absolute numbers (table) and percentages (chart).

Figure 4 Risk status of the world's avian breeds by species in October 2010 in terms of absolute numbers (table) and percentages (chart).

breeds (including 10 now thought to be extinct). Almost all evolved in situations in which grain was primarily used for human food. The pigs therefore became adapted to the use of fibrous by-product feeds from grain and vegetable production. They also were relatively slow growing (to synchronize their nutrient requirements to their limited food supply), quite fat (because animal fat was an important energy source for peasant farmers), and, in some cases, highly prolific. In the 1980s, government policies in China were changed to provide greater access to grain for animal feed, and rising incomes since that time have further supported that decision. Under these conditions, the indigenous pig breeds were markedly inferior to the faster growing, leaner, and more feed-efficient Western breeds. Government-sponsored importations and entry of multinational pig breeding companies into the market resulted in widespread crossbreeding of indigenous pigs with Western breeds. An extensive network of government AI centers for pigs facilitated the use of imported breeds, and the development of more sophisticated urban markets heightened preferences for leaner pork. By the early 1990s, many of the AI stations no longer provided boars of the local breeds.

The events in Chinese pig breeding were fully rational responses to changed government policy and to changes in the economy and the nature of society. Both farmers and consumers benefited from the changes. However, the result has been to endanger a whole array of local breeds, many of which possess globally unique characteristics.

In developed nations, focus on a declining number of elite breeds in relatively intensive production systems has likewise endangered many traditional breeds. The situation is particularly acute in Europe, and greater cognizance of the problem exists there. FAO (2010b) lists 3537 breeds of European livestock. Of these, 505 are considered extinct and no information on population size is available for an additional 758. Of the remaining 2274 breeds, fewer than two-thirds (1151 breeds) were considered secure or listed as "maintained."

In response to this contraction in livestock genetic diversity, many nations of Western Europe have established programs to maintain endangered breeds. Although often using a combination of *in situ* and *ex situ* techniques, high priority is placed on *in situ* conservation. The importance of livestock breeds as a cultural and historical resource reflecting the heritage of the nation or as a component of unique and perhaps themselves endangered agroecosystems is particularly recognized in Europe. The contribution of livestock breeds to public welfare is sometimes referred to as "landscape value," and public resources are being directed toward breed conservation activities. These programs may involve maintenance of endangered breeds on public facilities or direct payments to farmers who maintain endangered breeds.

Throughout the developed nations, "grassroots" organizations play a significant role in *in vivo* conservation of endangered livestock breeds. These nongovernmental organizations (NGOs) have for many years provided leadership for conservation of livestock diversity. Examples include the Rare Breeds Survival Trust in the UK (<http://www.rbst.org.uk>), the American Livestock Breeds Conservancy in the United States (<http://www.albc-usa.org>), the Safeguard for Agricultural Varieties in Europe (<http://www.save-foundation.net>), and the Canadian Foundation for the Conservation of Farm Animal

Genetic Resources (<http://www.cfagr.com>). The success of these organizations attests to the potential to involve committed private individuals in breed conservation. They have been most successful in wealthy countries in which significant private resources can be exploited, but the identification of private patrons to aid in breed conservation can also occur in developing nations. The success of these organizations relies on members who are committed to, and educated about, the technical aspects of genetic conservation. Otherwise, well-meaning but misdirected breeding policies may result in losses of genetic diversity. Public-private partnerships to provide members of these NGOs with technical expertise can be particularly beneficial.

Ex Situ Strategies

Ex situ conservation usually involves cryopreservation of gametes, embryos, tissues, or somatic cells or the storage of DNA, but may also involve live animals kept in farm parks, research farms, or other noncommercial settings. In the developed nations, farm parks have increased in popularity and often contribute to meaningful maintenance of biodiversity through their association with responsible grassroots organizations. Live-animal, *ex situ* conservation can also occur at public-funded facilities, generally under conditions that at least approximate those found in commercial agriculture but which often do not replicate the particular conditions under which the breeds were evolved and traditionally used. In these situations, selection for unique adaptational characteristics is relaxed, but with proper breeding management and adequate population size, key genetic characteristics of the breed can be retained for many generations. Costs of *ex situ* live-animal conservation are high, however, involving feeding and daily care of breeding animals, and disease outbreaks or localized disasters may threaten endemic breeds (Carson *et al.*, 2009). The risks associated with live-animal *ex situ* programs are therefore also high, especially in developing nations in which sustained funding for long-term conservation programs may not be available and risks of social and political upheaval are greatest.

Use of cryopreserved gametes, embryos, and tissues is a more common form of *ex situ* conservation. In farm animals, sperm cells can be successfully frozen and stored for future use in all species, although success rates from use of frozen sperm vary considerably among species. Techniques for collection, cryopreservation, and subsequent use of sperm cells are relatively well developed; a single collection provides a relatively large number of gametes, and multiple samples are relatively easy to obtain. For these reasons, cryopreserved sperm cells are the most common material used for *ex situ* conservation of endangered breeds. Cryopreserved sperm are ideally suited to support *in situ* conservation activities. Storage of sperm from a wide sample of males of a breed provides future access to the genetic material of these representative foundation animals. Losses of genetic diversity in living populations can thus, if necessary, be restored by use of sperm from males of past generations.

However, cryopreserved sperm cells are not particularly efficient for regeneration of a breed that has become extinct. Sperm cells contain a sample of only half of the animal's DNA; therefore, restoration of an extinct breed from cryopreserved sperm requires a "grading-up" process in which sperm

is used on females of a different breed over several generations to eventually create animals that have a majority of their nuclear genes from the cryopreserved breed. The efficiency of use of sperm cells to restore a breed depends on the generation time and the fecundity of the species. For example, restoration of 93.75% of the nuclear genes (i.e., four generations of upgrading) can be accomplished in approximately 3.5 years in pigs, and use of 100 sows initially could conservatively result in production of 1000 breeding females by generation four. In contrast, in cattle a minimum of 10 years would be required using conventional breeding techniques to produce even a small number of animals possessing 93.75% of the nuclear genes of the preserved breed. Although nuclear genes can be adequately preserved using frozen sperm, cytoplasmic DNA found in animal mitochondria are contributed only via the ovum and can thus be preserved only by storage of cryopreserved ova or embryos. Cryopreservation and subsequent *in vitro* fertilization of ova are not yet practical for domestic species. Embryo cryopreservation, however, is practical in cattle, sheep, and goat and permits conservation of the full genome, both nuclear and cytoplasmic. However, collection of embryos for cryopreservation is more difficult and expensive than collection of sperm cells and yields of embryos are much lower, often on the order of only 2–8 embryos per mating. Also, cryopreservation of embryos is difficult in pigs and not practiced for poultry.

Recommendations for *ex situ* conservation programs thus generally focus on extensive use of frozen sperm cells. However, access to modest numbers of cryopreserved embryos (in species for which this is possible) and/or small populations of breeding females preserved under either *in situ* or *ex situ* conditions is recommended to provide a source of cytoplasmic genes and allow efficient regeneration of the breed. Cryopreserved embryos produced by mating 25 pairs of unrelated parents and bolstered by cryopreserved sperm from 25 unrelated males can effectively capture the genetic diversity of a breed for long-term conservation and future use.

Cryopreservation of somatic cells is also becoming common in *ex situ* conservation programs as an economically efficient approach to back up *in situ* populations and insure animal genetic resources against extinction. Several companies offer cloning services on a commercial basis, but with a focus on unique, high-value individuals rather than populations. Use of cloning in breed conservation thus relies on the assumption that continuing research will eventually result in substantial increase in efficiency of cloning new individuals from cryopreserved adult cells. Use of cloning to support conservation of rare breeds will be discussed in the section Advances in Cloning.

Impacts of New Technologies

Advances in Cryopreservation

Technological advances in cryopreservation continue to enhance our ability to preserve biodiversity. Key research areas in cryopreservation include:

- Improved cryopreservation of pig embryos to allow capture of the full genome including mitochondrial DNA. This is

especially important in Asia, where the number of endangered pig breeds is large.

- Improved cryopreservation of poultry embryos and semen. In chickens, success rates from use of cryopreserved semen remain low. Better success rates would prompt greater use of frozen semen in the poultry industry, which would then facilitate storage and access to frozen gametes for conservation purposes. Cryopreservation of fertilized eggs will likely remain difficult, but extraction and cryopreservation of the germinal disk of cells from the fertilized egg separate from the egg itself appears possible. Recent studies have also successfully cryopreserved both male and female gonadal tissue in poultry, with subsequent successful transplantation into live recipients.
- Improved understanding of why semen from some males and embryos from some breeds do not survive freezing well. Large individual differences exist in success rates for cryopreservation of semen and embryos. In commercial cattle breeding, there is considerable selection for “freezability” of semen, and because the populations are large this selection has little impact on the genetic diversity within the breed. However, endangered breeds are commonly represented by only a few males, and if semen from several of these cannot be satisfactorily cryopreserved, a significant segment of the biodiversity of the breed may be lost. Success rates for frozen embryos are also often lower in poorly characterized endangered breeds, and these breeds sometimes respond poorly to the hormonal regimen required for embryo collection. More reliable and robust techniques for semen and embryo recovery and cryopreservation are thus needed.
- Reproductive biotechnologies and cryobiologies for minor livestock species. Most developments in reproductive biotechnologies have targeted the most common and commercially important livestock species, and *Bos taurus* cattle in particular. For many other species, these technologies remain far behind, if investigated at all.

Advances in Molecular Characterization and Gene Mapping

The emergence of molecular tools for characterization of animal DNA has revolutionized the study of livestock genetic diversity. Techniques developed for sequencing of the human genome in 2003 were rapidly applied to genomes of a variety of livestock species, most notably cattle, pig, and chicken, but also horse, dog, sheep, turkey, etc., and with increasing emphasis on regionally important species such as water buffalo, camel, and alpaca (<http://www.ncbi.nlm.nih.gov>).

Molecular analyses have increasingly contributed to understanding patterns of domestication of livestock species and confirmed the existence of multiple centers of domestication for several species (Groeneveld *et al.*, 2010). Objective methods to describe genetic relationships among livestock breeds now provide information for setting conservation priorities. The establishment of effective conservation programs for the thousands of livestock breeds shown in Figures 3 and 4 is neither possible nor necessary to protect a high proportion of the diversity present within the species. However, identification of high-priority candidates for conservation requires objective

information on their genetic uniqueness relative to other breeds. Thus in 1993, FAO developed recommended sets of microsatellite markers that are to be used to assess genetic relationships among breeds within each of the major livestock species (FAO, 1998). These markers have been widely used to clarify relationships among breeds within each of the domestic species (Baumung *et al.*, 2004). More sensitive molecular tools, such as high-density SNP (single-nucleotide polymorphism) arrays and increasingly powerful software packages now provide a range of options for setting conservation priorities (Boettcher *et al.*, 2010) and predicting breed composition for individuals that lack pedigree documentation of ancestry. However, to date, the proportion of the global livestock breeds that has been characterized at a molecular level remains small. Genetic distances derived from microsatellite markers have been used for reconstruction of phylogenetic trees but are rarely used for conservation decisions.

In common with the primary immediate use of genome sequence information in humans, rapid genetic diagnosis of simply inherited genetic defects, diseases, and other conditions in livestock is now relatively straightforward for species with published genome sequences and high-density SNP arrays. Resulting DNA-based diagnostic tests provide necessary information to identify asymptomatic carriers of the defect and manage breeding decisions. In the past, discoveries of serious genetic defects in popular breeding lines in livestock often resulted in extended periods of confusion and re-criminations, required extensive and expensive progeny testing of potentially affected sires, and resulted in unnecessary losses of elite breeding stock. However, with today's improved diagnostic capabilities, the identification and management of such defects becomes straightforward and creates minimal disruptions in breeding programs. A recent example is discovery of the causative mutation for the lavender foal defect in Arabian horses (Brooks *et al.*, 2010).

Most of the economically important characteristics of farm animals are under polygenic control, involving several to many generally as-yet-unidentified genes scattered across the genome. Simply inherited mutations with large effects on phenotype have been identified for a few characteristics in livestock. Notable among these are mutations in several genes that promote increases in frequency of twin and triplet births in sheep (Davis, 2005) and a number of point mutations in the myostatin gene that result in increased muscle mass in several different species (Rodgers and Garikipati, 2008). Most of these mutations are associated with failures of developmental regulation and would have been deleterious in nature where litters of three or more lambs or the overproduction of muscle tissue or milk is not adaptive, but may be advantageous for intensively managed domestic species. However, most of the genetic variation used in practical breeding programs remains largely uncharacterized, and is often portrayed as consisting of some number of "quantitative trait loci," (QTLs), influencing production traits in as-yet-unknown ways. The use of molecular techniques to access these QTLs and to develop diagnostic tests that can identify animals with favorable sets of QTLs for specific traits is a central area of current study in the breeding of animals. A variety of techniques exist for detection and localization of QTLs. All are based on detection of associations between production levels and

various sorts of genomic DNA markers such as microsatellite or, increasingly, SNP variants. The Animal Quantitative Trait Locus database (<http://www.genome.iastate.edu/cgi-bin/QTLD/index>) lists 13,931 reported QTLs for 1369 different characteristics from 739 publications in cattle, pigs, sheep, and chickens. However, relatively few of these reported QTLs have been successfully validated and shown to have unambiguous effects in other populations and breeds or successfully fine-mapped to identify causal mutations, and only a few have been used in marker-assisted breeding programs.

Current focus for use of molecular information in animal breeding applications involves high-density SNP arrays that can be used to probe the genome for 50,000–750,000 individual genetic markers and detect associations between these markers and accurate and objective measures of animal performance (Hayes and Goddard, 2010). The ability of these arrays to detect QTLs of large effect and facilitate identification of favorable mutations or other genetic modifications remains an area of interest. However, current research in livestock is often based on the assumption that relatively small individual effects of relatively large numbers of markers can be summed across the genome to provide an informative picture of the average genetic merit of potential breeding animals for various economically important characteristics, even if individual gene effects and mechanisms of action remain, for the moment, unknown. Once the necessary associations have been documented, these genome-wide association studies allow generations of molecular estimates of genetic merit in descendants of the original research population. This process has been proposed to allow direct prediction of genetic merit from genomic, rather than performance-based, information. However, the large numbers of phenotypic measurements needed to establish these associations are often not available, especially in small breed populations or breeds kept in extensive systems. The likely long-term impact of these research efforts for practical animal breeding practices and the conservation of animal genetic resources thus remain controversial, especially in developing countries (Hayes *et al.*, 2009a, b; Hoffmann, 2010; Marshall *et al.*, 2011).

Advances in Cloning

Cloning of farm animals from adult cells, if perfected and commercialized, could have far-reaching effects on both use of biodiversity and the efficiency of its conservation. Widespread use of genetically identical cloned individuals in commercial production systems would reduce the biodiversity present within those systems and increase the vulnerability of the animals to specific diseases or other environmental stressors. However, the ability to efficiently produce clonal offspring from adult animals whose performance has already been characterized has potential to facilitate synchronization of genetic resources to specific production conditions. In this scenario, breeding animals that have demonstrated exceptional adaptation and productivity in a particular environment could be clonally reproduced for use in that specific environment.

The ability to produce clonal offspring from adult cells would have tremendous implications for conservation of

endangered genetic resources. Large numbers of cells could be harvested from individual animals using minimally invasive biopsy techniques and cryopreserved for future use. Production of clonal offspring from these cryopreserved cells would recreate the full nuclear genome of the preserved animals, though the mitochondrial genome would presumably be lost during the process of nuclear transplantation to a donor cell. Furthermore, because sampling of somatic cells for cloning is relatively easy, large numbers of founder animals could be sampled, increasing the biodiversity present within the sample. Complications involved in harvesting and conservation of gametes and embryos would be circumvented by somatic cloning and efficiency of storage of animal genetic material would approach that achieved in plants by storage of seeds.

Techniques for clonal propagation of adult animals remain less efficient than use of frozen semen or embryos, but early results hold great promise. Dolly, the sheep produced by cloning of adult mammary cells at the Roslin Institute in Scotland, represented a watershed event in this technology. Many other livestock species have now been successfully cloned from adult cells, several companies offer animal cloning on a commercial basis, and cloned pigs can be obtained for a few thousand US dollars. In New Zealand, one of the last individuals of an endangered Enderby Island cow was cloned to attempt to save the breed (RBCSNZ, 2002).

Prospects and Threats

An assessment of likely trends in global livestock genetic diversity must recognize that population growth, economic development, and urbanization will require significant increases in animal productivity worldwide. Increasing demand for animal-based foods, as well as increasing resource constraints involving use of farm land for biofuel production, environmental degradation of grazing lands, effects of climate change, and strategies for climate change mitigation, may also have an impact on breed and species utilization. In the short to intermediate term, the result will likely be an even greater emphasis on monogastric livestock species and on those breeds that are the most efficient converters of feed into meat, milk, and eggs. Long-term impacts are, however, difficult to predict.

The normal processes of breed evolution have accelerated during the past 50 years. Breeds are disappearing at more rapid rates than in the past, and the rate of new breed formation has not correspondingly increased. Many indigenous breeds are ill-suited to contribute in meeting the challenges of sustainable intensification of livestock production in a global economy in a timely manner, and these breeds will likely become endangered or restricted to subsistence production systems, especially in ecologically marginal areas (Hoffmann, 2011). The contribution of highly productive, highly selected global breeds to world food production will continue to expand, placing further pressure on currently less-productive indigenous breeds.

Climate change is an additional challenge for the livestock sector. Highly productive global breeds managed in controlled

production environments may be effectively buffered from direct physiological effects of higher temperatures and changing precipitation patterns, but only if costs for feed, energy, and water remain low. Also, the consequences of climate change will likely include a variety of indirect effects that may be felt via ecosystem-wide changes that influence supplies of feed, alter the incidence of various diseases, or lead to political instability. All these factors will, in the short term, increase the risk of decline of indigenous breeds. However, the adaptational characteristics of local breeds have value in synchronizing animal genetic resources with local stressors and should contribute to development of new, improved breeds that can better cope with changing production conditions. Current breeding goals have begun to place increasing weight on functional traits, but further adjustments may be required in the future to address higher temperatures, lower-quality diets, and greater disease challenges (Hoffmann, 2010). Species and breeds that are well adapted to such conditions may become more widely used.

Given the potential for significant future changes in livestock production conditions and objectives, a synthesis of the utilizationist and preservationist views on genetic resource management is needed. There is need to utilize genetic resources from a variety of sources and manage them in ways that will maximize livestock productivity in sustainable production systems. Such a synthesis must likewise be accompanied by programs to protect breeds which may be endangered or replaced, and requires better characterization of breeds, production environments, and associated knowledge; the compilation of more complete breed inventories; improved mechanisms to monitor and respond to threats to genetic diversity; more effective *in situ* and *ex situ* conservation measures; genetic improvement programs targeting adaptive traits in high-output and performance traits in locally adapted breeds; increased support for developing countries in their management of animal genetic resources; and wider access to genetic resources and associated knowledge. Also, additional research in the valuation of nonmarket products and services, including ecosystem services, provided by diverse livestock breeds is needed in order to reduce the disparity between private and public interest in farm animal genetic resource conservation.

Glossary

Grazing intensity Frequency and closeness of grazing.

Grazing pressure Stocking rate, the units of grazing animals per land area.

Overcompensatory growth In grazed plants, the reaction to tissue removal by enhanced primary production compared to in undefoliated controls.

Domestication of Ruminants: The Process that Changed the Face of the Earth

The natural capacity of ruminants to digest hard plant tissue and to transform it into animal biomass is a service that has been provided by biodiversity to human societies for millennia. The cultural evolution of humans is strongly related to the exploitation of this service, which has influenced—and in turn has been influenced by—the pace, the pattern, and the distribution of societies. The first traces of domestication have been found in the Iranian mountains, where there are paleolithic settlements of sheep and goat herders dating from ca. 10,000 B.P., suggesting that domestic ruminant keeping precedes proper agriculture. Evidence of organized livestock breeding culminates between 8000 and 6000 B.P., at several sites in the Middle East and Anatolia. Ali Kosh, located at the head of the Persian Gulf in the ancient kingdom of Susiana (7000 to 6500 B.P.), is such a site where villages of farmers-breeders are found. Animals and plants were originally domesticated in a specific region, and then diffused during a 10,000 year process to many other parts of the world.

In the past, nomadic tribes and their herds of domesticated animals roamed freely to avoid drought, in search of good grazing land. In the rangelands of North America, Native Americans followed the wandering herds of buffalo, and it was not until domesticated cattle and sheep were introduced by European colonists that the vegetation and soils of the plains and mountains were put under stress. The rise of national boundaries has created a barrier to many such movements. Seasonal transhumance is still a practice in Mediterranean areas, where especially flocks of sheep are moved between winter quarters in the mild rainy lowlands and summer quarters in rich alpine pastures.

On a global scale, diffusion was drastically accelerated by European expansion from the fifteenth century onward. At present, rangelands cover a large part of the world's land surface (40%). Eighty percent of these rangelands are in arid and semiarid areas, where most of the 50 million humans who are directly dependent on livestock breeding for their subsistence live. In Africa, livestock breeding—mostly cattle and goats—is the main source of income south of the Sahara, especially in countries like Sudan, Chad, and Somalia. This is also the case in much of Asia, in particular in Mongolia, the central Asian republics of the former USSR, and Tibet. Cattle and sheep are

also economically important domestic animals in New Zealand, Australia, Europe, and parts of the United States.

The domestication of animal species, especially of ruminants, and the associated land management and breeding practices are historically important ecosystem disturbance agents through the effects of grazing, trampling, and digging. They have transformed, shaped, and selected landscape and vegetation types, and have had significant, often dramatic, effect on many ecosystem properties, including plant and animal diversity. Uncontrolled grazing on shrublands and the creation of pastures have gone hand in hand with the creation of agricultural land. Native plant and animal communities have been greatly modified by the introduction of domestic animals, either directly or through habitat alteration and landscape change. There are many well-documented examples from all around the world, but those that occurred on islands are the most informative for our purposes.

The direct effects of the introduction of domestic grazers on native faunas since prehistoric times are well described for the Mediterranean islands, where original faunas have been affected by species extinction and introductions promoted by humans. The modern mammalian faunas on the big islands of the Mediterranean (e.g., Corsica, Sicily, Crete, and Cyprus) replaced the entirely endemic Holocene faunas that existed before human arrival. After the spontaneous extinctions of the late Pleistocene, the surviving endemic herbivores (e.g., *Epsoriculus* spp; *Prolagus sardus*, *Rhagamys orthodon*, *Meridiopitomyx henseli*) were rapidly eliminated, even before A.D. 7000, either intentionally by hunting or indirectly through the effects of commensal species. The faunas of today are the result of a severe human-induced selection in favor of species belonging to the geographic and cultural universe of the human groups that immigrated to the islands, within which domestic livestock predominate.

In southern Greenland, the arrival of the Norsemen in ca. A.D. 1000, and the introduction of cattle have disturbed the fragile dwarf-shrub heaths, which had established slowly after the deglaciation period. The activities of Norsemen, but especially of their cattle, destroyed the equilibrium between climate and vegetation, causing severe erosion of the unstable soil. When the Norsemen disappeared in the fifteenth century, a new phase of soil stabilization began, but this is now being severely disrupted with the immigration of more humans, now as sheep-breeders, in the beginning of the twentieth century.

Madagascar's highland region was once covered with evergreen forests dominated by about 20 endemic tree species. Beginning around A.D. 600, Indonesian settlers started to remove forests to create swidden fields. At about A.D. 1000, zebu cattle were introduced from Africa, further increasing the need to expand grassland at the expense of forests. These forests were being permanently replaced by a floristically impoverished steppe vegetation on ferrolitic soils. By A.D. 1600, the highland forest had mostly disappeared: tree and humus removal had led to massive erosion, floods, water shortages, and faunal extinctions or endangerment.

Although much poorer in species richness, the faunas of the French subantarctic islands (Amsterdam, Saint Paul, Kerguelen, and Crozet Islands) show an analogous history following their discovery in the sixteenth and seventeenth centuries. Sheep, mouflon, and cattle are among the nine introduced species that thrive owing to lack of competitors and predators, and despite the small number of founding individuals. Herbivores have induced particularly significant changes in the nature and the structure of plant communities, leading to the extinction of endemic plants (e.g., *Phyllica nitida*) or the degradation of the fragile peat-bogs that constitute the nesting sites of the rare Amsterdam albatross (*Diomedea amsterdamensis*).

In North America's Great Basin Desert, changes in plant communities that occurred after the introduction of domestic livestock in the late 1800s resulted in unusual, unforeseen cascade effects on the interactions between native mammalian species. The establishment and dissemination of cheatgrass (*Bromus tectorum*) in the Great Basin has played a central role in this process. Evidence suggests that cheatgrass was introduced accidentally as a grain contaminant at the end of the nineteenth century, at the same time that large-scale domestic animal grazing began. Imported from Mediterranean Europe and central and southwestern Asia, seeds of cheatgrass exploited an ecological niche, as no native annual was dominant in the Great Basin. Cattle, sheep, and feral horses facilitated its establishment, for they spread the seeds in the same areas that they disturbed. Once established, cheatgrass promoted the likelihood of fire to the detriment of the native species. In addition, other factors, such as the effects of the lack of vesicular-arbuscular mycorrhizae and selective lagomorph grazing, have worked in concert to further establish cheat grass dominance. The ecological consequences of this establishment have been an increase in fire frequency and intensity, a decrease in species diversity, and a landscape that is susceptible to severe erosion.

Ecosystem change resulted in the subsequent irruption of mule deer (*Odocoileus hemionus*) and the expansion of mountain lions (*Felis concolor*). Domestic sheep depredation is currently increasing in western North America and is related to the expansion of suitable mountain lion habitat, and consequently of the lion's distribution and abundance. Furthermore, the expansion of this predator's population has caused the severe reduction of the porcupine (*Erethizon dorsatum*), another North American native species.

Although environmental determinism is not the dominant explanation of agricultural geography, the limits of the distributions of domestic animals, especially of their races, are often attributed from a physiological point of view to the physical environment, temperature, and water availability on a regional scale. However, it is also quite clear that the driving forces

behind some of these ecological changes stem largely from cultural and social factors, including the size and growth of human populations, which determine the scale and the practice of stock-keeping activities.

Ecosystem-Level and Global Effects of Large Domestic Animals

The ecological role of cattle, sheep, and goats, that is, the effects they have on ecosystem processes and biodiversity, is far more complex than the fact that they remove biomass by eating grass and often browse, or feed on, twigs, shoots, and leaves of other plant species. The floristic composition and productivity of the grazed ecosystem and the persistence of vegetation and of plant and animal species, as well as physical and biogeochemical processes, may suffer substantial changes because of grazing animal-related factors, such as the severity and frequency of grazing, species of animal, method of prehension, treading, excreta deposition, and even the saliva deposited on plants. In some environments, the effects of grazing are quite predictable, whereas in others such effects are much more difficult to predict. Under certain conditions, grazing can act as a completely density- and species-independent disturbance, and under other conditions the effects on plants can be very selective and effects on soil properties and chemistry very heterogeneous in space.

Impacts on Vegetation

The impact of domestic ruminants on vegetation is typically studied through comparisons between grazed and ungrazed ecosystems. The dependent variables in these studies are descriptors of vegetation structure, commonly diversity and productivity. The independent variables are ecosystem or environmental parameters as well as grazing variables. Grazing variables are regulated by humans. Depending on different grazing regimes, the range of these variables extends from the unregulated (by humans) grazing of native species, to uncontrolled- or free-grazing of domestic ruminants, to overgrazing situations, and to optimized stocking rates for profitable animal mass gain per unit area of grazed land.

A meta-analysis of data on the effects of grazing on vegetation and soils, from more than 230 studied sites worldwide, has shown that the typical symptoms of the disturbances caused by domestic ruminants are changes in species composition, changes in dominant species, life-forms, and growth forms, changes in aboveground net primary production, and, finally, effects on the relationship between species, aboveground net primary production, root mass, and soil nutrients. In general, herbivory prohibits the most productive species from dominating and suppressing through competition the less productive ones. The conceptual model of Milchunas, Sala, and Lauenroth (1988) predicts the variation in plant diversity in relation to grazing intensity along gradients of moisture and evolutionary history of grazing (Table 1). According to this model, grazing should have a greater effect on species composition in more humid areas because adaptations of tall growth forms capable of competing for light in a dense

canopy are opposite to those that provide resistance to or avoidance of grazing. In contrast, plant adaptations to frequent loss of organs from drought or herbivory are similar, and under arid and semiarid conditions, competition is primarily for belowground resources. The explanation of the evolutionary history of grazing gradient in the conceptual model is that increasing grazing history over evolutionary time results in greater capacities for regrowth following herbivory, and thus favors prostrate growth forms. In communities of long evolutionary history and high aboveground net primary productivity, grazing causes rapid shifts in the dynamic balance between suites of species adapted to either grazing avoidance/tolerance or competition in the canopy.

Field research offers evidence that herbivory by domestic ruminants may cause either an increase or a decrease in plant diversity. For example, in salt marsh habitats, heavy grazing eliminates sensitive species and produces a dense cover of graminoids in upper marsh coastal habitats. In other marshes, grazing produces bare patches that allow annuals and other low marsh species to invade upper marsh zonal communities. A retrogression in plant succession may occur in salt marshes and salt deserts because of heavy grazing. Intermediate levels of grazing by sheep, cattle, and horses could produce communities with the highest species richness and heterogeneity. At the other extreme of the aridity gradient, in a seasonally dry tropical savanna, species diversity was higher in a grazed area than in the neighboring area where grazers were permanently excluded. Furthermore, similarity in species composition between the grazed and ungrazed areas was very low.

The introduction of domesticated animals to a pasture or rangeland invariably causes changes in species composition, leading to an increase in the abundance of those species that are less palatable to animals. Low-growing, prostrate growth forms are selected by grazing, and annuals and shrubs appear to be favored. Tall perennials decrease in abundance because this growth form, which offers competitive advantages in dense canopies free from grazing conditions, exposes the plants to selective herbivory pressure in grazed ecosystems.

Between sites, aboveground primary productivity is negatively affected by grazing in the most productive ecosystems. Within sites, lowlands are more affected than uplands. More productive lands are more likely to be preferred by grazing animals and breeders.

Grazing has negative impacts on root systems. Intensive grazing removes the product of vegetative growth, which in turn reduces root growth. Under drought conditions, shallow roots cannot fully exploit subsoil moisture reserves, and the plant becomes stressed.

Erosion, Desertification, and Land Degradation

Cattle are important agents of geomorphological change. The animals' impact on the landscape is to create bare soil by weakening the vegetation cover and then by breaking this cover down by trampling. On uplands, heavy grazing compacts the soil, reduces infiltration, increases runoff, and increases erosion and sediment yield. However, light and moderate grazing has effects that are much less significant. In riparian zones, grazing decreases erosional resistance by reducing vegetation and exposing more vulnerable substrate. Trampling directly erodes riverbanks, thus increasing turbulence and consequent erosion. Trampling also maintains and expands the area of bare soil upon which frost, rain, and wind act.

Livestock keeping when practiced in a nonsustainable way is one of the major causes of desertification. Desertification is defined as land degradation in arid, semiarid, and dry subhumid areas resulting from temporary climatic crises, especially droughts that occur periodically, and harmful human activities in vulnerable ecosystems. Land degradation leads to a reduced capacity of dryland areas to produce useful outputs—crops, fodder for grazing livestock, bush and tree cover—or to sustain wildlife. Degradation of dryland areas involves a range of processes: the erosion of soils through water and wind, falling levels of soil fertility and damage to soil structure, loss of vegetation cover and change in species composition, reduced availability and decline in the quality of water supplies, loss of wildlife, and a decline in the biological diversity of plant and animal life. Such processes reduce the productivity of crops and livestock systems in dryland areas, and increase the vulnerability to food crisis of populations depending on these resources.

The processes of desertification were first recognized in the Sahelian region of West Africa. Overstocking and overgrazing, firewood collection, and cultivation of unsuitable soils are responsible for 80% or more of the desertized lands in Africa. However, dryland degradation is now accepted as a worldwide problem. Over the last decade, surveys have been carried out on a global level to assess the extent of desertification and soil degradation by region, and they have produced significantly differing results. The GLASOD survey (Global Assessment of Soil Degradation), commissioned by the United Nations Food and Agriculture Organization (FAO), showed that 19.5% of drylands worldwide were suffering from desertification. In contrast, the United Nations Environment Programme (UNEP) usually quotes an estimate of 70% of the world's dryland areas as suffering from some degree of desertification, with an estimated 900 million people worldwide at risk from

problems of degradation. This survey includes not only areas affected by soil erosion, but also where a change in vegetation had occurred (e.g., where perennial grasses had been replaced by annuals). All regions of Africa have been affected by drought conditions and human pressures on land, as have parts of Mediterranean Europe, North America, Asia, and Latin America. In Spain alone, data from 1993 suggest that almost 1 million hectares (ha) of land are already considered as desert lands and another 7 million ha have been identified as being at high risk of desertification. In the United States, 90 million ha are considered to be affected by desertification.

The underlying factors that cause such adverse effects are many and various, and operate at different levels. At the local level, for example, inappropriate range, water, and livestock management practices may accelerate rates of erosion, especially on sloping land. Information continues to accumulate on the effects of digging deep boreholes in several regions of Africa. These boreholes discharge several liters of water per second, without the enforcement of any range management or land use policy, and have too often resulted in large concentrations of livestock (20,000 to 40,000 head) during the dry season. This destroys the range in the vicinity of the well over a radius of 20 km (125,000 ha) in one or two seasons (the stock rate being 10–15 times the carrying capacity).

At the national level, government policies on land tenure and use determine whether production processes will be sustainable or not. During the second half of the twentieth century, the Autonomous Russian Republic of Kalmykia has undergone severe desertification. Under Soviet rule, rangelands were increasingly devoted to animal production, and pastures were converted to cropland in a campaign to increase crop productivity. Pastures were grazed at rates that were two or three times their sustainable production, saiga antelope (*Saiga tatarica*) populations and habitat greatly decreased, more than 17 million ha were subjected to wind erosion,

380,000 ha were transformed into moving sands, and 106,000 ha were ruined by secondary salinization and water-logging. By the 1990s, almost 80% of the Republic had undergone desertification, and 13% had been transformed into a true desert.

At the international level, rising prices provide encouragement to breeders and farmers to produce more and, at the same time, raise revenues that can be invested to increase capacity. The African arid zone harbors about 55% of that continent's 550 million head of livestock, and these livestock numbers have increased by 75% from 1950 to 1985, in spite of severe droughts that occurred in most arid zones in the early 1970s and 1980s. This is exponential growth of about 0.7% per year, compared to the 1.0–1.5% demographic growth rate of the African pastoralist population.

Nutrient Cycling and Over-Enrichment in Grazed Ecosystems

Nutrient cycles in a grazed ecosystem do not differ from those in an ungrazed one in terms of individual element pools, flows, potential input and output pathways, and inter-relationships among various nutrient pools (Figure 1). On the contrary, the sizes of the pools, the rates of biogeochemical processes, the flows, and the residence time in the various pools of elements and nutrients are greatly affected by herbivores and the breeding practice and stock size. For example, in natural pastures, animals remove aboveground plant biomass (shoots, stems, and leaves) and deposit excrement; in managed pastures, where grazing intensity exceeds the natural carrying capacity, additional herbage and other fodder is provided to the animals and, thus, additional inputs of nutrients are entering the system. The cycle of nitrogen, most likely the most perplexing of all nutrients, is certainly disturbed under grazing conditions. In natural pastures, less litter returns to the soil, the topsoil organic matter declines, and the

Figure 1 Pools and fluxes of nitrogen (N) in a typical pasture. Nitrogen pools are shown in their relative average sizes: ORG-N, organic soil N (about two orders of magnitude larger than other pools); M-N, microbial biomass N; SF-N, soil faunal biomass N; INORG-N, inorganic (NH_4^+ , NO_2^- , and NO_3^-) soil N; PLANT-N, plant biomass N (ABG: shoots; BLG: roots); and HERB-N, large herbivore biomass N. The large rectangle represents field boundaries. For clarity, not all directions of flux are shown.

nutrient cycles are quantitatively disturbed. Grazers shorten the N cycle, increase the rate of N cycling, and cause significant redistribution of N, among pools and in space. On a daily basis, cattle excrete a somewhat constant amount of N in feces (8 lb/1000 lb of dry herbage consumed), the remainder being excreted in urine. Because they excrete more at night than during the day, bedding or watering places receive higher quantities of excreta-carried nutrients. Cattle and sheep retain a small fraction of the N consumed, and thus they have an impact on the control of N cycling that is out of proportion to their low biomass on an areal basis.

Areas of pasture that receive dung and urine may undergo marked changes in botanical composition. Urine spots and fecal pats contain the equivalent of 500 to 1000 lb N/acre, which is of different availability to plants: the N in dung is mainly in organic form, with a slow overall mineralization, whereas in urine N is present as urea, which is hydrolyzed rapidly to forms available to plants. The plant recovery of nutrients from excreta spots is rarely greater than 30%. Generally, the nitrogen in urine stimulates grass growth and the phosphorus in dung stimulates legume growth, especially on P-deficient soils. However, plants immediately beneath dung pats may be killed and urine occasionally scorches them.

The cycles of nitrogen, phosphorus, and other nutrients are not generally closed at the field or farm level. For nitrogen, six main pathways of loss have been described in grazed ecosystems: NH_3 volatilization, denitrification, wind and water erosion, NO_3^- leaching, fire, and incorporation into animal biomass (exported or retained *in situ*). The relative importance of these pathways depends on environmental conditions and breeding practices. In humid and subhumid ecosystems, N losses are related to leaching, whereas volatilization is most important in semiarid regions, and the export of animal products and erosion in deserts.

Runoff from agricultural land and livestock feedlots is among the major "nonpoint" sources of nutrients entering marine and freshwater ecosystems, causing pollution and eutrophication. This has been shown on very large scales, as in the United States, where these widely dispersed activities are the major source of water pollution, as well as at the level of local ecosystems, such as lakes, rivers, and estuaries. In aquatic ecosystems, overenrichment with P and N causes a wide range of problems, including toxic algal blooms, loss of oxygen, fish kills, loss of seagrass beds and other submerged aquatic vegetation, degradation of coral reefs, and loss of biodiversity—including species important to commercial and sport fisheries and shellfish industries.

Lake studies allow contemporary sediment and nutrient dynamics to be placed in a historical context so that trends and rates of change in catchment inputs may be calculated. Surface runoff from heavily grazed grassland has a high suspended sediment, ammonium nitrogen, and particulate phosphorus load. The combined effect of the long-term increase in the organic loading from livestock and the inorganic N and P load from fertilizers may be the source of nutrient enrichment in lakes. The literature offers several examples of eutrophication studies in lakes and streams; for example, in the already extinct karstic Jastericie Lake in Slovakia, in the coastal freshwater systems of Slapton Ley and Loe Pool in southwestern England, and in the streams draining the Mount

Lofty ranges in South Australia, livestock breeding is the main source of organic N and P that affects the trophic status of surface waters.

Intensive animal production generally involves feeding large numbers of animals in small areas. For example, 4% of the cattle feedlots in the United States produce 84% of the cattle. Nutrients in manure can be recycled by applying the manure to cropland. However, the amount of manure generated by concentrated livestock operations often far exceeds the capacity of nearby croplands to use and retain the nutrients. Thus, excess fertilization and manure production cause a surplus of N and P, which accumulate in the soil. Some of this surplus is transported in soil runoff to aquatic ecosystems. Especially for N, the surplus is mobile in many soils, and much leaches into surface waters or percolates into groundwater. Indeed, the density of animals on land is directly related to nutrient outflow to aquatic ecosystems. Surplus N can also volatilize in nitrous (NO_2) and ammonia (NH_3) forms to the atmosphere. The emission of ammonia from stored and land-applied manure can result in a significant loss of nitrogen for crop production. A high atmospheric concentration of ammonia can result in the acidification of land and water surfaces, cause plant damage, and reduce plant biodiversity in natural systems.

Nitrous oxide, together with carbon dioxide and methane, are considered to be major greenhouse gases. Besides emissions of these gases from the plant-soil compartment of the pasture soil system, CO_2 and CH_4 emissions from cattle and their excreta are significant components of the global fluxes. Methane emitted from dung is a very important contributor to the global methane budget; the corresponding figure is as high as 20%. Grazing animals on managed pastures and rangelands have also been identified recently as significant contributors to the global N_2O budget. This occurs because of the concentration of herbage N in urine and dung patches, and by the compaction of the soil due to treading and trampling. The limited amount of experimental data indicates that 0.1 to 0.7% of the N in dung and 0.1 to 3.8% of the N in urine is emitted to the atmosphere as N_2O . Integral effects of grazing animals have been obtained by comparing grazed pastures with mown-only grassland. Grazing-derived emissions, expressed as a percentage of the amount of N excreted by grazing animals in dung and urine, range from 0.2 to 9.9% with an overall mean of 2%. Using the emission factor and data statistics from FAO for numbers of animals, the global contribution of grazing animals is estimated at 1.55 Tg N_2O -N per year.

Biotic Relationships of Large Domestic Animals

Reactions of Plants to Grazing

The direct act of grazing represents a loss of organs or parts of organs to individual plants and an alteration of canopy structure to the community. Resistance of plants to grazing involves avoidance and/or tolerance mechanisms.

Plant tolerance reactions to the grazing event will depend on the capacity of individual plants to compensate for lost organs and the relative impact of the removal on competitive

relationships in the canopy. Various species of animals graze differently because of their prehension organ anatomy and method, behavior, and diet preferences. For instance, cattle graze individual plant parts (leaves or stems) less selectively than do sheep and goats. The literature offers examples of strong interactions among intensity, severity, and other properties of grazing of different animal species and pasture (species) in terms of various components of plant fitness. Especially for grass species, the height, tiller number, survival, and reproduction are the fitness components that are most usually monitored in grazed plots/individuals and ungrazed controls.

Three alternative hypotheses on the effects of grazing intensity on plant growth and fitness have been proposed (Figure 2). The first hypothesis predicts that net primary productivity shows a consistent decline as the intensity of grazing increases. The second hypothesis predicts that plants compensate for tissue removal up to some level, beyond which productivity begins to decline. The third hypothesis, known as “overcompensatory growth,” states that within some levels of herbivorous feeding, plant productivity may be enhanced before declining beyond a threshold of grazing intensity. This hypothesis has generated an ongoing debate on the controversy of plant response to grazing, such as herbivore optimization and overcompensation.

Observations of mixed cattle and American elk grazing in high-elevation rangeland conditions in southwestern North America show that vegetation has deteriorated. Experiments in the North American tallgrass prairie suggest that overcompensation is a nonequilibrium plant response to grazing. Photosynthate that would be stored as reserves and used for root growth and flower and seed production is instead used to replace lost leaf area, thereby resulting in higher foliage productivity. However, under chronic grazing or mowing, vegetation is prevented from maintaining high nutrient and water uptake capacity (large root biomass) and accumulating reserves that allow overcompensation responses.

Herbivory by large animals is known to function as a selection pressure to increase herbivory resistance within plant populations by decreasing the frequency of genotypes possessing large erect canopies. Data on the trade-off between herbivory resistance and competitive ability in *Schizachyrium scoparium* confirm that herbivory by domestic cattle may function as a selection pressure to induce architectural variation in grass populations within an ecological time frame (ca. 25 years).

Comparative studies between species suggest that there is no consistent pattern of grazing effects on survival, reproduction, recruitment, and regeneration. In one study, five abundant native Kansas tallgrass prairie perennial forbs (*Baptisia bracteata*, *Oenothera speciosa*, *Vernonia baldwinii*, *Solidago missouriensis*, and *Salvia azurea*) were chosen to examine the effects of native (bison) and domestic (cattle) ungulates on plant growth and reproduction. The results show that their responses are complex and vary significantly among plant species, ungulate species, and plant life-history stages. *Baptisia bracteata*, *O. speciosa*, and *V. baldwinii* increased in growth and reproduction in grazed sites, indicating competitive release in response to selective grazing of the dominant warm-season matrix grasses. Species with reduced performance in grazed

Figure 2 Theoretical relationships between the variation of net primary productivity (NPP) of grazed and ungrazed grassland pastures and the grazing intensity. Lines represent possible trends in NPP as grazing intensity increases, according to the three examined hypotheses: consistent decline hypothesis, partial compensation hypothesis, and overcompensatory growth hypothesis.

sites are likely to be negatively affected by disturbances generated by ungulate nongrazing activities, because none of the forbs studied was directly consumed by bison or cattle. Furthermore, the native and domestic ungulates differ significantly in their effects on forb growth and reproduction.

Among 18 species of shrubs and trees in southeastern Australia, 10 showed significant negative effects on recruitment and/or regeneration from present or past sheep grazing. In this case it was shown that the negative effect of sheep grazing on recruited seedlings must exceed that of natural thinning before overall regeneration is affected. Evidence that grazing by sheep and goat increases the total inclusive fitness in the Mediterranean shrub *Anthyllis cytisoides* has been reported: in this species, moderate grazing promotes growth, stability of vegetative structures, and adult survival, and a drop in seed production. Direct consumption of reproductive organs has significant effects on the overall fitness of the grazed species. In the annual wild wheat *Triticum dicoccoides*, removal of maturing inflorescences by cattle reduces its fitness by 50%, estimated as the number of seeds produced per seedling. In this species, protection from grazing leads to a significant increase in the number of individuals that produce mature inflorescences as well as in the number of spikelets per

inflorescence. In the clonal species *Yucca elata*, cattle browsing of inflorescences may reduce reproductive effort, but the most significant changes in population structure are due to the browsing of small caudices, including both genets and ramets. Thus, the expansion and dominance of “resistant” species on heavily grazed land may be a result not only of reduced competition, as is commonly assumed, but also of enhanced performance of some of these species.

Grazing avoidance mechanisms reduce the likelihood of defoliation by animals. For example, leaf surface chemistry of plants is related to the extent of defoliation by livestock. Data on cattle, sheep, and goat herbivory on tarbush (*Flourensia cernua*), an abundant but generally unpalatable Chihuahuan Desert shrub, support the hypothesis that secondary chemicals—mostly terpenes and phenolic compounds—in its resinous leaves may influence the diet selected by the ruminants. Although individual leaf surface compounds do not appear to greatly affect the degree of use of the plant by livestock, collectively these compounds may partially explain the differential herbivory on tarbush plants by livestock. Mimicry, both chemical and morphological, has also been suggested as a grazing avoidance mechanism for plants. Experimental tests with sheep showed that odor alone is not persistently effective in preventing herbivory, but that both taste and odor must be similar for one plant to successfully mimic another.

Spines and thorns are considered to be defense structures against herbivory by both wild and domestic animals. Experimental evidence from *Acacia drepanolobium* suggests that spine length is an inducible defense, with longer spines being produced by branches experiencing a greater level of herbivory. Examination of *Acacia* trees protected from herbivory for several years suggests that reduction in spine length eventually exceeds 70%. The effectiveness of spines and thorns as an anti-herbivore defense in several plants in arid Australia did not vary with the evolutionary history of the herbivores (i.e., wild versus domestic). Furthermore, additional evidence shows that the interaction of ants of the genus *Crematogaster* and thorns of *A. drepanolobium* is a means of defense against browsing goats. This interaction causes the animal to stop feeding almost immediately, therefore keeping the amount of foliage lost to a minimum. It is hypothesized that the acacia-ant relationship evolved partly because of the pressure from browsing herbivores.

Seed Dispersal and Germination

Throughout the world, the presence of wild or domestic ruminant herbivores is correlated with the maintenance of high levels of plant diversity in natural and semi-natural grazed systems, where the grazing pressure does not exceed the carrying capacity of the vegetation. Zoochorous dispersal by herbivorous mammals has been verified repeatedly and its possible influence on the structure, function, and diversity of plant communities, mainly herbaceous, has been suggested.

Cattle, sheep, and goats are important vectors for endo- and epi-zoochorous seed dispersal. On large scales, seed dispersal systems associated with domestic ruminants have been proved to be particularly favorable for the introduction of alien plant species, and herbivores have facilitated the

naturalization and spread of many alien herbaceous species from their initial points of introduction. The case of central Iberian herbaceous species introduced into the Mediterranean-type zone of Chile is very relevant: almost 15% of the central Iberian herbaceous species are naturalized in Chile, with the endo- and epi-zoochorous species representing 21 and 23% of them, respectively. The expansion of the distribution of individual species is often correlated with the effects of cattle ingestion on the viability and germination rates of seeds. For example, the calden (*Prosopis caldenia* Burkart) is the dominant tree of the xerophytic open forest in the semi-arid pampa of Argentina. Calden has gradually increased its distribution throughout the region during the past century as a result of livestock grazing in the pampa forest. Excreted calden seeds display a range of delayed germination responses. This variation would increase the probability of seed germination for a variety of environmental and site conditions.

The potential dispersal distances for adhesive seeds attached to the fur of cattle range from tens of meters to kilometers. The morphology of the seed's structure and its position on the animal's body influences the length of time that it remains attached to the fur.

Endozoochorous dispersal selects for traits that enhance ingestion and passage of viable seeds through the animal. Passage of buffalo grass (*Buchloe dactyloides*) seeds, one of the two dominant grasses of the North American shortgrass prairie, through cattle has a positive effect on germination and seedling growth from intact diaspores; the damage due to mastication is minimal, and the retention time is from 1 to 5 days. This combination of retention time and movements of the animals influences the spatial expansion, distribution, and abundance of this species. Clear experimental evidence that the germinability of seeds increases significantly following their passage through the cattle gut has been provided for the legume *Biserrula pelecinus*, which is greatly favored by its dispersal through cattle dung.

The amounts and diversity of viable seeds contained in the feces of domestic ruminants grazing in nature may be quite high. Based on germination trials, the number of seed species germinated in the dung of feral cattle feeding in savannas and floodplain wetlands in Rajasthan, India, was about 450 seeds per m², belonging to 35 species. Similar results have been obtained in Mediterranean open woodlands, where cow dung may yield as much as 70 seeds per gram of dry dung from a large number of species (about 75 species). Although ruminant species differ in their traits and feeding habits, dispersal seems to be mainly determined by seed production of the plant community.

Large isolated trees are a common feature of the agricultural landscape in humid tropical regions that were originally covered by rain forest. These isolated trees are used as a source of shade for cattle, but they also function as nursery plants for rain forest species by facilitating the establishment of zoochorous species whose seeds are deposited under their canopies by cattle, frugivorous birds, and bats. The same pattern is observed in Botswanan savannas: the analysis of seed pools under the canopy trees *Dichrostachys cinerea* showed that epizoochorous species such as *Tragus berteronianus* were dominant at the cattle resting sites under trees.

Patch dynamics are also affected by seed zoochorous dispersal. In Mediterranean pastures, cattle-dispersed endozoochorous seeds germinate in manure and colonize the dung patches. The micro-succession involved is independent of the type of pasture. A small-scale spatial pattern results in which gaps of old dung are dominated by endozoochorous species. Thus, dung patches enhance the similarity between different communities when they are grazed, but also increase the variation within communities. In Australian sub-alpine grassland vegetation, the density of shrub seedlings in gaps varied considerably in space, but it is related to the dispersal of seeds and the trampling and browsing effects of domestic cattle.

Large seeds such as *Quercus suber* acorns are rapidly predated by large herbivores. However, in this case, experimental data seem to suggest that seedling emergence rate is inversely related to the intensity of predation on the acorn bank.

Domestic Animals as a Food Source for Wild Predators

Domestic ruminants have largely replaced wild grazing animals over large areas on all five continents. Natural predators and scavengers of large mammals have easily adapted to this alternative food source. Population densities of cattle, sheep, and goats are equivalent and often higher than the densities of the wild grazers that have been replaced, as the animal keepers' tendency is to maximize herd or flock size and food may be supplemented at times of natural fodder shortage. Furthermore, domestication has usually produced heavier, slower-moving, less alert, and less experienced animals, which often have their ability to move impaired by various means and structures such as pens, fences, and tethering. Thus, domesticated animals are generally speaking easy prey for most natural predators. The way of life of pastoral societies around the world has been profoundly influenced by the constant strive for protection of their flocks and herds from natural predators.

Wolves (*Canis lupus*) are legendary in Western culture as predators of cattle, goats, and especially sheep. Today they have been exterminated or reduced to small populations over much of their former range in the Northern Hemisphere, but where they do exist they are still important predators of livestock. In regions like parts of southern Europe, where stock-raising is prevalent and wild prey are rare, their presence is still connected with the raising of stock animals. The wolves either prey directly on live individuals, most often stray ones, or feed on carcasses and offal. Similarly, dingos (*Canis familiaris*) can be serious predators of sheep in Australia, as are coyotes (*Canis latrans*) in North America. In Africa, Asia, and North and South America, large cats such as leopards (*Panthera pardus*), tigers (*Panthera tigris*), and pumas (*Puma concolor*) commonly prey on cattle, sheep, and goats. Big cats and the other canids differ from wolves in that their existence does not seem to rely to any significant extent on domestic animals. The big cats are especially dependent on extensive tracts of undisturbed habitat where natural prey is available, and consequently domestic animals are consumed opportunistically and usually only by certain individuals.

In many parts of Eurasia, both golden eagles (*Aquila chrysaetos*) and lammergeiers (*Gypaetus barbatus*, German for

"lamb vulture") have traditionally been regarded as significant predators of lambs, and this has been the reason for their local extermination. In reality they kill very few lambs but commonly feed on dead lambs or the carcasses of older sheep. Both Old and New World vultures also include dead cattle, sheep, and goats in their diet. As in the case of the wolf, in parts of the world where wild ungulates are now rare, such as around the Mediterranean, these sources of food are essential for the survival of vulture populations. Although griffon vultures (*Gyps fulvus*) are not migratory, they perform movements between summer and winter quarters, closely following flocks of sheep as they move from high-altitude summer pastures to lowland grazing land in winter. For the larger eagles and vultures, open range grazing has a dual functionality in providing a food source (essential or supplemental) and by indirectly maintaining open habitats where such species are able to forage.

Cattle, sheep, and goats appear in the diet of the majority of other medium or large natural predators such as bears (*Ursus* spp.), foxes (*Vulpes* spp.), jackals (*Canis* spp.), other eagles (*Aquila* spp.), and buzzards (hawks, *Buteo* spp.) to a varying extent, depending on the region, the species of predator, and the method of stock-keeping. In most such cases, carcasses, offal, and still borns are consumed rather than healthy, full-grown adults.

Domestic Animals and Invertebrate Fauna

Both positive and negative effects of cattle, sheep, and goats on invertebrate communities of grazed ecosystems have been reported. In grazing systems where the carrying capacity of vegetation is not exceeded by grazing, as in the traditionally managed European mountain meadows or mixed woodlands, the maintenance of a landscape mosaics favors the persistence of high plant diversity and abundance of flowers and has positive consequences on insect population dynamics. Bumblebees, butterflies, syrphids, and other insect groups foraging on flowers depend on the landscape management in which domestic grazers play an important role. In central Spain, traditional landscape management for non-intensive grazing by goats and cattle favors the conservation status of the butterfly *Euphydryas aurinia*, which depends on patches of open oak woodlands mixed with open areas, where important nectar sources and larval foodplants are present. However, indirect effects on pollinators may appear from the removal of flowers by grazing: in *Yucca elata*, cattle preferentially consume inflorescences, which are found to be highly nutritious. This implies the possible local extinction of the yucca moth *Tegeticula yuccasella*, the exclusive pollinator of the plant.

In the shortgrass prairie of Colorado, in the United States, heavy grazing negatively affects the colony density and distribution of harvester ants (*Pogonomyrmex occidentalis*) on a broad scale, with important consequences to behavioral, community, and ecosystem processes. Browsing by goats has been proven to increase the damages from both tunneling (Diptera) and "blotch-making" (Lepidoptera) leaf miners on trees growing on the Aldabra Atoll.

Insects are particularly sensitive indicator taxa of land use (especially the Cicindellidae, Staphylinidae, and Carabidae).

Domestic cattle influence the arthropod diversity through trampling, its intensity being more important than the type of trampling. In semi-arid tropical soils in Queensland, Australia, heavy grazing significantly affects Acari populations as well as the diversity and activity of termite species. The deterioration of soil hydraulic properties associated with cattle trampling at high stock rates is responsible for these negative effects on detritivorous termite activity in the topsoil.

A wide range of invertebrates, as well as bacteria and fungi, are involved in the breakdown and eventual decomposition of dung. Some are facultative generalist decomposers of organic matter, but there are also a large number of specialist dung consumers, such as dungflies (Scathophagidae) and dung beetles (Geotrupidae, Scarabaeidae). The array of dung-feeding invertebrates present in a given area is mainly dependent on the characteristics of the dung, that is, on the taxonomy of the dung producer and its diet rather than on a distinction between wild and domestic stock.

Domestic Animals and Birds and Small Mammals

Excluding predators and scavengers, the main influence of cattle, sheep, and goats on other animals occurs indirectly through the creation and maintenance of open pasture land, in particular in areas where the natural vegetation cover would be forest or scrub. Tall-grass meadows, short turf on stabilized sand dunes, alpine meadows, dry stony pastures, and all other forms of grazing land that exist on different soils and under different climatic regimes are all attractive to species that would otherwise be restricted to steppe, desert, or arctic habitats on a global scale or to the margins of wetlands, beaches, steep hill slopes, and woodland clearings on a more local scale. The creation of pastures has gone hand in hand with the creation of agricultural land, which has also provided vast areas of open habitat. The expansion of both pasturelands and croplands began several thousand years ago, and the process of colonization and spread of open-country species into such newly created habitats is lost in prehistory and is largely a matter of conjecture.

Animal species closely connected with grazing land include mammals such as moles (*Talpa* spp.) and voles (Microtinae), birds such as larks (Alaudidae) and plovers (Charadriidae), and insects such as grasshoppers (Acrididae) and ants (Formicoidea). Grazing is often employed as a management tool, for example, to create the very short turf required by wintering white-fronted geese (*Anser albifrons*) in Britain.

Other species may use cattle, sheep, or goats more directly in feeding. Two well-known cases are cattle egrets (*Bubulcus ibis*) and yellow wagtails (*Motacilla flava*). Cattle egrets commonly use cattle, as well as other domestic and wild ungulates, as a vantage point and vehicle, capturing large insects disturbed by the cattle as they move. Yellow wagtails may also do the same or they may feed on flies and other insects attracted to the animals themselves or their dung.

Negative impacts on other animal species may also occur. For example, when natural grazing land is used, domestic ruminants may compete with wild herbivores. Although wild herbivores may suffer, human interest is usually focused on the reverse impact of wild herbivores on domestic

ones [e.g., rabbits (*Oryctolagus cuniculus*) and sheep in Australia].

Another negative impact on wildlife is the trampling of eggs and young of ground-nesting birds. This problem is more frequent in wetland habitats, where most bird species nest on the ground, and may be particularly damaging for colonially breeding species such as terns (Sternidae) and avocets (*Recurvirostra* spp.). Although these birds generally select islets or other sites that are inaccessible to ground predators (e.g., foxes) and thus also inaccessible to livestock, problems may be caused when water levels change or when a herd or flock is intentionally transferred to such a site.

Domestic Ruminants as Hosts for Parasites and Pathogens

Domestic ruminants harbor significant numbers of internal and external parasites. Helminths, protozoa, and arthropods (especially ticks and mites) are the most common components of the parasitic communities, although many other species of occasional or temporary parasites, such as blood-sucking Diptera, also infect domesticated animals. Endoparasites, mainly gastrointestinal parasites, have received most attention in veterinary research because of their prevalence as disease-causing organisms that are economically important in rearing commercial livestock. Within a species, the taxonomic diversity of parasites varies between the various organs of the hosting organism. Thus, the digestive tract, the liver, the circulatory system, the respiratory tract, the skin and the subcutaneous tissue, the muscles and the tendons, the eyes, the central nervous system, and the serous cavities are affected by quite distinct species of parasites such as trematodes, cestodes, nematodes, protozoa, and arthropods. For example, in sheep and goats, the list of gastrointestinal parasites comprises 15 trematodes, 9 cestodes, 88 nematodes, and 25 protozoa; the parasitic fauna in the skin and the subcutaneous tissues comprises only 6 nematodes but 78 arthropods. Parasitic communities also differ between host animal species, even closely related races. Likely causes are differences in host suitability and feeding differences that affect the probability of transmission.

Besides the specificity of the host-parasite interactions, the diversity of the domestic ruminants' parasite communities is strongly influenced by species-area and species-climate relationships. As an example, for nematodes it has been demonstrated that (a) large areas of permanent pasture include a variety of microenvironments that are favorable to the development of the free-living stages of various species of nematodes and (b) free-living stages are very susceptible to dryness and survive better in areas with heavy rainfall.

The widespread use of veterinary chemicals against endoparasites, pests, and other pathogens of domestic animals characterizes the high-input livestock breeding and production strategy. Avermectins, a relatively new class of broad-spectrum pesticides, are used widely to control livestock parasites. Following veterinary treatment, avermectins are eliminated in the livestock feces. The dung mesofauna potentially exposed to avermectin (or other active compound) residues includes insects, earthworms, springtails, mites, and nematodes. The effects range from acute toxicity in larvae and

adults, through disruption of metamorphosis, to interference with reproduction. For example, at high drug concentration in the dung, larvae of the dipteran *Cyclorhapha* are killed or paralyzed, while at lower levels their metamorphosis is inhibited. At very low concentrations of avermectins, well below levels occurring in feces after routine treatment, adult emergence is reduced and a significant number of imagines show morphological abnormalities. Nematoceran Diptera are less sensitive than *Cyclorhapha*, but larval and pupal development are affected at higher dose levels.

Dung mesofauna occupy a variety of different niches within the ecosystem and the faunal composition changes as the pats age. Some members of this fauna act in concert with soil microbial flora and assist in the breakdown of dung and consequent nutrient recycling on pasture-lands. A retardation in the rate of loss of biomass of dung pats from avermectin-treated cattle has been observed following the various forms of drug administration. Rare insects could be put at risk by the use of avermectins, especially those that breed exclusively in the dung of the herbivores on which avermectins are used.

The use of avermectins may also indirectly affect some species of vertebrates by depleting the quality and quantity of important food resources. The effects of any reduction in invertebrate food in livestock dung would be expected to be especially severe if it occurred at critical times for the vertebrates, such as during the breeding season or when newly independent young animals were foraging and fending for themselves. Insects that develop in livestock dung therefore have important, additional roles in the ecology of pasture-lands other than aiding dung degradation processes. Livestock dung is an important feeding habitat for a number of vertebrate species. The potential for direct poisoning of vertebrates through the accumulation of avermectins following consumption of invertebrates containing residues would, on present knowledge, appear to be limited, but it should not be disregarded.

This issue has generated much controversy regarding the extent of the effects on pasture and rangeland biodiversity and ecosystem functioning. It has been suggested that ecotoxicological studies commonly disregard the veterinary use patterns of drugs and consequently they overestimate their negative effects at a populational level. Avermectins administration patterns in temperate regions indicate that peak

periods of insect activity and peak times of avermectin use are often asynchronous. When avermectin usage and insect activity do coincide, the heterogeneous patterns of administration to livestock and the focus of treatment on young animals result in the deposition of feces that are predominantly free of avermectin residues. Results of large-scale, long-term studies indicate that, even under conditions of relatively high levels of avermectin use in cattle, the impact on non-target insect populations and their function is limited.

Glossary

Agroforestry A collective name for land-use systems and practices in which woody perennials are deliberately integrated with crops and animals on the same land management unit. The integration can be either in a spatial mixture or in a temporal sequence.

Contour hedgerow intercropping Also called alley cropping; crops are grown in the interspaces between rows of planted woody shrub or tree species that usually are legumes, and in which the woody species are periodically pruned during the cropping season.

Crop mixture Two or more than two crop (tree) species are grown simultaneously on the same field in alternative row(s) or mixture with no distinct row arrangement.

Intercropping Growing two or more crops simultaneously on the same field. According to row arrangement and cogrowth time, intercropping can be divided into three types: mixed, relay, and strip intercropping. Mixed intercropping refers to growing two or more crops simultaneously with no distinct row arrangement. Relay intercropping means growing two or

more crops simultaneously during part of the life cycle of each. A second crop is planted after the first crop has reached its reproductive stage of growth but before it is ready for harvest. Strip intercropping means growing two or more crops simultaneously in different strips that are wide enough to permit independent cultivation but narrow enough for the crops to interact agronomically.

Land equivalent ratio (LER) The area needed for sole cropping to produce the same amount of crops as produced in 1 ha of intercropping or mixed cropping.

Light use efficiency (LUE) Crop light use efficiency is defined as the slope of the linear relationship between accumulated biomass and cumulative intercepted light.

Monoculture Growth of the same sole crop on the same field.

Root length density (RLD) Root length per unit soil volume (m m^{-3} or cm cm^{-3}).

Root weight density (RWD) Root fresh or dry weight in unit soil volume (g cm^{-3}).

Sole cropping One crop variety grown alone in pure stand at normal density.

Crop Mixtures

Crop mixtures are of agricultural significance because appropriate mixtures can provide increased yields or decreased need for inputs such as fertilizers and pesticides, as reviewed in later sections of this article. Crop mixtures refer to cropping systems in which different crop (or tree) species or different varieties of the same crop species are grown simultaneously, or partly so, in the same field. Crop mixtures usually include agroforestry, hedgerow intercropping (or alley cropping), mixed intercropping, strip intercropping, and relay intercropping. Crops or varieties are not necessarily sown at the same time or harvested at the same time, but they have cogrowth stages for some period. Agroforestry is a collective name for land-use systems and practices in which woody perennials are deliberately integrated with crops on the same land management unit. Contour hedgerow intercropping (also called alley cropping) crops are grown in the interspaces between rows of planted woody shrub or tree species, usually legumes, and in which the woody species are periodically pruned during the cropping season. Intercropping means growing two or more crops simultaneously either in no distinct row arrangement or in rows or strips on the same field. The strips are wide enough to permit independent cultivation but narrow enough for the crops to interact agronomically. Intercropping can be classified into mixed intercropping and row or strip intercropping based on the row arrangement and the relay intercropping cogrowth time of two crops.

Importance of Crop Mixtures

Crop mixture, mainly as agroforestry or intercropping, is practiced globally, including in Africa, Asia, Europe, and the Americas. Although there is no firm estimate of the global extent of mixed cropping systems, its importance can be illustrated by several examples.

Africa and Latin American

Cassava (*Manihot esculenta* Crantz), the fourth most important energy staple of the tropics, provides food and income for some 750 million people (Leihner, 1983). It is often found in mixed stands together with a variety of other food or cash crops. Recent estimates indicate that 40% and 50% (or more), respectively, of the cassava grown in America and Africa is intercropped (Leihner, 1983). Bananas are very important in Kenya for domestic consumption and export, and are extensively grown, mainly intercropped with short-term crops. There has been an increase in the grower interest in using intercropping to develop new cropping systems for their land (Ouma, 2009). Intercropping constituted 91% of the cropping systems in Ethiopia (Fininsa and Yuen, 2001). Legume-cereal intercropping, especially maize/beans intercropping, is common throughout East and Southern Africa (Mucheru-Muna et al., 2010). Agroforestry is also popular all over the world. For example, there are 2.8 million hectares of jungle rubber agroforests and 3.5 million hectares of all multistrata

agroforests in Indonesia, 7.4 million hectares in India, 5–6 million hectares in Niger, 5.1 million hectares (90% of agricultural land) in Mali, 9.2 million hectares of silvopastoral systems and 0.77 million Coffee agroforests in Central America, 6 million hectares of dehesa agroforestry in Spain/Portugal, and 7.8 million hectares of cocoa agroforests worldwide (Zomer *et al.*, 2009).

Asia

There are thousands of intercropping systems in China, including agroforestry, cereals/cereals, legumes/cereals, cereals/vegetables intercropping, etc. The northern plain region, a major agricultural area covering Hebei, Henan, Shandong, Beijing, Tianjin, and parts of Anhui, Jiangsu, Shanxi, and Shaanxi, is typical in agroforestry. Various agroforestry schemes have also been adopted in the region within 4.5 million hectares of the total area (Yin and He, 1997). Paulownia (*Paulownia elongata*)-based intercropping is the most popular, accounting for approximately two-thirds of the total area (Yin and He, 1997). Poplars are also the major tree component of traditional agroforestry systems throughout the south temperate central area of China, which includes all or portions of Jiangsu, Anhui, Zhejiang, Hubei, Henan, Shandong, and Shanxi provinces, an area covering approximately 600,000 km² (Fang *et al.*, 2010). Hedgerow intercropping has become increasingly popular in China since the 1970s. There were, for example, 700,000 ha in Shanxi Province and 10,000 ha in northern Shaanxi Province in 1999 (Sun *et al.*, 2008).

Intercropping systems of cereals/cereals, grain legume/cereals, and cereals/vegetables are common in China. A total of 25–28 million hectares of intercropping was distributed across all of the provinces in the country except for Tibet and Qinghai Province in the 1980s, and the area reached 33 million hectares in the 1990s (Zou and Li, 2002). It is estimated that there was 1.5 million hectares of soybean-cultivated area, which was mainly intercropped with various other crops in southern China in 2008 (Zhou *et al.*, 2010). Wheat/maize intercropping (Figure 1(a)) has been an important cropping system for raising grain yields per unit of arable land in northwestern China. The area under wheat/maize intercropping was 75,000 ha in Ningxia Hui Autonomous Region in 1995, which produced 43% of total grain yields for the region, and there is 200,000 ha of wheat/maize intercropping annually in Gansu, with more than 12 tons of grain yields per hectare (Li *et al.*, 2001a). In China, intercropping has been developed into a pattern of high output and high input, which is completely different from the traditional pattern of low input and low output. Intercropping featured with high yield (output) and high input plays an important role in Chinese modern agriculture. In tropical regions of Asia, intercropping is much more common.

Main Patterns of Crop Mixtures

Intercropping is practiced in both tropical and temperate areas. In Central Africa, maize, sorghum, or millet is grown with pumpkin (*Cucurbita* spp.), cowpeas (*Vigna unguiculata*), pigeon peas (*Cajanus cajan* L.), or beans (*Phaseolus* spp.). Cocoa

(*Theobroma cacao* L.) is grown with yams (*Dioscorea* spp.) or cassava (*M. esculenta* Crantz). In the tropical Americas, maize is grown with beans and squash (*Cucurbita* spp.). In both Africa and Latin America, beans and peas (*Pisum sativum* L.) climb tall cornstalks, whereas pumpkins and squash cover the ground below (Machado, 2009). In Asia, intercropping with similar patterns is practiced by farmers in tropical areas of China, India, Iran, Nepal, Sri Lanka, and Thailand.

Intercropping is also practiced in temperate regions. For instance, there are many kinds of intercropping in northwestern China, such as spring wheat/spring maize (Figure 1(a) and 1(c)), maize/soybean/linum (*Linum usitatissimum* L.) (Figure 1(b) and 1(d)), winter wheat/spring maize, wheat/soybean (Figure 1(e)), wheat/faba bean (*Vicia faba* L.), maize/potato (*Solanum tuberosum* L.) (Figure 1(f)), wheat/potato, wheat/sunflower (*Helianthus annuus* L.), wheat/vegetables (e.g., tomato (*Lycopersicon esculentum* Mill.), Peking cabbage (*Brassica pekinensis* Rupr.), and onion (*Allium* spp.)), maize/vegetables (e.g., garlic (*Allium sativum* L. (Figure 1(g))), maize/pea (*P. sativa* L.) (Figure 1(h)) intercropping, in areas with one cropping season because of the annual thermal limitation in the northwestern part of China (Ministry of Agriculture, China, 2006).

In tropical areas of Indonesia, India, Niger, and Mali, there are jungle rubber-based agroforestry and multistrata agroforestry. There are silvopastoral systems, coffee agroforests in Central America, dehesa agroforestry in Spain/Portugal, and cocoa agroforestry worldwide (Zomer *et al.*, 2009). China practices agroforestry based not only on rubber tree (*Hevea* spp. Aubl.), tea tree (*Camellia* spp.), and citrus (*Citrus* L.) (Figure 1(o) and 1(p)) in its tropical and subtropical regions, but also on fruit trees (e.g., apple (*Malus* Mill.), pear (*Pyrus* L.), apricot (*Armeniaca* Mill.) (Figure 1(i)), peach (*Amygdalus* L.), and jujube (*Ziziphus jujuba* Mill.) (Figure 1(j)), pepper (*Zanthoxylum bungeanum* Maxim.), and mulberry (*Morus* L.) in its temperate regions (Ministry of Agriculture, China, 2006).

In Europe, too, some kind of intercropping has been identified, such as barley (*Hordeum sativum* L.)/pea (*P. sativum* L.) intercropping in Denmark, the United Kingdom, France, Italy, and Germany, and wheat/pea intercropping in Denmark, popcorn/melon and potato/cabbage (*Brassica oleracea* var. *capitata* L.) intercropping in the United Kingdom, berseem clover (*Trifolium alexandrinum* L.)/barley, common vetch (*Vicia sativa* L.)/wheat, triticale (*Triticosecale* Wittmack), barley, or oat (*Avena sativa* L.) intercropping in Greece, fennel (*Foeniculum vulgare* Mill.)/dill (*Anethum graveolens* L.) intercropping in Italy, maize/bush bean (*Phaseolus vulgaris* L.) intercropping in Spain, leek (*Allium porrum* L.)/celery (*Apium graveolens* L. var. *dulce* (Mill.) Pers.) intercropping in Switzerland, and various vegetables/vegetables intercropping (e.g., cabbage, cauliflower (*B. oleracea* var. *botrytis* L.), or strawberry (*Fragaria xananassa* L.) intercropped with bean, cos lettuce (*Lactuca sativa* L.), leaf lettuce (*L. sativa* L.), onion (*Allium cepa* L.), or radish (*Raphanus sativus* L.) in Turkey.

In the Americas, peas are intercropped with barley or oat, and in Canada, wheat is intercropped with canola or pea and broccoli is intercropped with peas, beans, potatoes, oats, cauliflower, or cabbage; in the USA, maize and soybeans are intercropped. In Brazil, there are many kinds of intercropping as in other tropical areas.

Overyielding

Land Equivalent Ratio (LER)

LER is defined as the relative land area with sole cropping required to produce the yields achieved by intercropping (Willey, 1990). It is calculated using the following formula:

$$LER = \frac{Y_{ia}}{Y_{sa}} + \frac{Y_{ib}}{Y_{sb}}$$

where Y_{ia} and Y_{ib} are yields of crops a and b in intercropping, respectively, and Y_{sa} and Y_{sb} are yields of crops a and b in sole cropping, respectively. LER indicates the area needed under sole cropping to produce the same amount of crops as produced in 1 ha of intercropping or mixed cropping. Therefore, there is yield advantage of intercropping if LER is greater than 1, and no yield advantage of intercropping if LER is less than 1.

The literature published in the past 15 years has summarized LER values. In most cases, intercropping has had a significant yield advantage, with LERs greater than 1 indicating overyield compared to sole cropping. However, when some similar crops were intercropped (e.g., faba bean (*V. faba* L.)/pea intercropping), there was no overyield (Li *et al.*, 1999).

Yields

Yield advantages have been reported for many crop mixtures. Overyielding of intercropping can be classified into three types: 1. *Overyielding of both intercropped crop components.* For example, in 4 years of field experiments, maize (*Zea mays* L.) overyielded on average 43% and faba bean overyielded on average 26% when grown on a low-phosphorus but high-nitrogen soil (Li *et al.*, 2007). A similar result was observed for potato/maize intercropping in Yunnan Province, southwestern China (Li *et al.*, 2009). 2. *One component overyields but the other component is comparable to its corresponding sole species.* For instance, there was 33–85% overyielding in tobacco/maize, sugarcane/maize, and wheat/faba bean intercropping systems in Yunnan province, China (Li *et al.*, 2009), in which the overyielding was mainly derived from additional crop maize in tobacco/maize and sugarcane/maize intercropping, and additional faba bean production in wheat/faba bean intercropping (Li *et al.*, 2009). *Faidherbia* is a nitrogen-fixing Acacia species that is indigenous to Africa and is widespread throughout the continent. It goes dormant and sheds its foliage during the early rainy season, at the time when field crops are established. Its leaves regrow only at the end of the wet season. This unusual phenology makes it highly compatible with food crops, since it does not compete with crops significantly for light, nutrients, or water during the growing season. On the contrary, annual crops in the vicinity of *Faidherbia* trees tend to exhibit improved performance and yield (Garrity *et al.*, 2010). 3. *One component crop overyields; the other component is reduced in mixture, but the total yield of the two component crops overyield.* For instance, in a mixture of faba bean and barley grown in Ethiopia, Agegnehu *et al.* (2006) found that increasing faba bean proportion from 12.5% to 62.5% increased faba bean seed yields from 12% to 48% but lowered barley grain yields from 93% to 73% of the respective sole crop yields. Total grain yield and barley yield equivalents

increased as the seeding percentage of faba bean in the mixture increased (Agegnehu *et al.*, 2006).

Mechanisms of Overyielding

Relative Importance of Above-Ground and Below-Ground Interactions Between Crop Species

Yield advantages of crop mixtures result from both above- and below-ground interactions between associated species (Semere and Froud-Williams, 2001; Thorsted *et al.*, 2006; Mariotti *et al.*, 2009). Donald (1958) found that root competition had a greater effect than shoot competition on crop growth and that there were positive root interactions among species. In 33 of 47 (70%) cases found in the literature, root competition had a greater effect than shoot competition on plant growth and resource capture (Wilson, 1988). In a maize/faba bean intercropping system, comparisons on the basis of LER clearly showed that the intercropping advantage was significantly decreased by plastic sheet and nylon mesh (37 μ m) barriers between root systems. When the roots of the two species intermingled, LER values based on total above-ground biomass and grain yields were 1.21 and 1.34, respectively, but when the roots of the two species were separated completely by plastic sheet or partly by nylon mesh, the LER values declined to 1.06 and 1.19, or 1.12 and 1.26, respectively (Li *et al.*, 1999). Recent reports also showed similar results between intercropped maize and pea (Semere and Froud-Williams, 2001), between intercropped winter wheat and white clover (*Trifolium repens*) (Thorsted *et al.*, 2006), and between faba bean and maize (Li *et al.*, 2007). In combinations of two winter cereals (barley and wheat) and two legumes (white lupin and common vetch), an example of low-input intercropping system, when a nitrogen-fixing species is present, the mixture of the roots of components is important for the utilization of the soil resources, and when a climbing species is also present, the mixture of shoots can result in an increased utilization of light (Mariotti *et al.*, 2009).

Above-Ground Interactions Between Species

When two or more crops are growing together, each must have adequate space to maximize interspecific facilitation and to minimize interspecific competition between the crops. Above-ground interactions between intercropped species can be mainly summarized into three aspects: (1) light competition and utilization, (2) canopy heat resource and crop development, and (3) spatial and temporal compensation of microclimate factors, such as radiation, temperature due to the structures of crop mixtures, space configuration, and time arrangement.

Light Interception (LI) and Light Use Efficiency (LUE)

LI and LUE are useful concepts for characterizing the resource capture and use efficiency of cropping systems, including intercropping. Crop LUE is defined as the slope of the often linear relationship between accumulated biomass and cumulative intercepted photosynthetically active radiation (PAR) (Monteith, 1977; Russell *et al.*, 1989). LI and its conversion to

dry matter by individual components have been quantified in several studies of conventional intercropping systems such as in leucaena/millet (Corlett *et al.*, 1992), in sorghum/groundnut (Harris *et al.*, 1987), in maize/bean (Tsubo *et al.*, 2001), and in wheat/cotton (Zhang *et al.*, 2008a). Improved productivity can result from either greater interception of light, a higher LUE, or a combination of the two (Willey, 1990). LI sometimes increases as a result of mixing two species and growing them together instead of growing each species alone, as a result of either a lengthening of the period of soil coverage in the intercrop (temporal advantage) or a more complete soil cover (spatial advantage) in the intercropping, compared to the ensemble of sole cropping (Keating and Carberry, 1993).

At a small spatial scale, the strip intercropped species capture more light than the canopy of sole crop species per unit of strip area, but not per unit of homogenized land area. In relay intercropping, although the intercropping period is not too long, the direct effect of shading is less than the indirect effect through a lower leaf area index (LAI) (incomplete canopy closure) as a result of retarded growth due to a development delay during the intercropping phase. Thus, to increase light capture, the intercropping systems should be improved by alleviating the delay in crop development by applying film cover or by increasing plant densities to reduce 'spatial' losses in LI (Zhang *et al.*, 2008a).

LUE will not be much affected in intercropping systems with component crops that differ in growing period, since the competition between component crops is less (Fukai and Trenbath, 1993). In most of the previous studies, LUEs of both intercropped species were not greatly affected by the mixture. The LUE of dominant component crops in intercropping systems is generally not affected. Examples include millet in millet/groundnut (Willey, 1990), sorghum in sorghum/groundnut (Matthews *et al.*, 1991), and maize in maize/cowpea (Watiki *et al.*, 1993). For the lower, shade crops, for example, groundnut and cowpea, it was reported that the LUE was sometimes 'slightly' affected, potentially as a result of competition for other resources, that is, water and nitrogen.

Canopy Heat Capture and Crop Development

A shaded intercropping crop always captures less radiation than that captured by taller crop, which causes decreases of canopy ventilation and soil temperatures and delays crop

development. In wheat/cotton relay strip intercropping, the cotton was delayed by 9–15 calendar days, compared to cotton in monoculture (Zhang *et al.*, 2008b). In wheat/soybean intercropping, the development of the relay intercropped crop was also affected at an early stage (Wallace *et al.*, 1992). However, when comparing the development delay to the results reported for other intercropping systems (Matthews *et al.*, 1991; Gethi *et al.*, 1993; Bukovinszky *et al.*, 2004), the delay in wheat/cotton intercropping is longer and has more serious consequences.

The most obvious modification of the environment in intercropping is shading of one species by another taller crop; as a consequence, the reduced capture of light results in a reduced growth and yield of shaded crop. Shading also modifies other environmental conditions, for example, ventilation and soil temperature (Midmore *et al.*, 1988; Midmore, 1993). By environmental modification, intercropping can even obtain higher yields than sole cropping (Midmore *et al.*, 1988); for example, under heat conditions, reduced soil temperature and moisture by intercropping may favor multiplication and growth of some soil microorganisms (Singh *et al.*, 1986). The environment can also be modified by management practices, for example, covering the soil by a film or straw (Rana *et al.*, 2004).

The decrease in both air and soil temperatures was mainly caused by shading of taller crops (Figure 2), because there were no differences in temperature between intercropping and monoculture when the air temperature was low due to the absence of direct radiation (Zhang *et al.*, 2008b). A soil cover consisting of plastic film effectively ameliorated soil temperature in intercropping. Licht and Al-Kaisi (2005) found an increased soil temperature as a result of tillage. Thus, tillage may also provide an option to raise soil temperature in intercrops. Increase in temperature may also be achieved by measures that diminish shading, such as using of shorter wheat cultivars or planting crops on ridges.

Spatial and Temporal Complementarity

Yield advantages from intercropping are often attributed to complementation between component crops in the mixture, resulting in a better total use of resources rather than growing crops separately. A good example of temporal complementarity of crop mixtures is relay intercropping system, in which there is an increase in the total LI because the

Figure 2 The shading effect in strip wheat/cotton (a) and maize/field pea (b) intercropping. Photos by Lizhen Zhang.

intercropped second crop has built its seedling with relative larger LAI after the first crop is harvested. Relay intercropping is commonly practiced in an area that has insufficient growing degree days for continuous double cropping system.

Plant architecture can be used strategically to allow one member of a mix to capture sunlight that would otherwise be unused. This is considered spatial complementarity. Widely spaced maize plants growing above an understory of beans and pumpkins are a classic example. Different mixture designs are used in practice and have been characterized as to their productivity in relation to the spatial configuration.

In strip intercropping systems, a border row effect has often been found. In maize/soybean strip intercropping, Ghaffarzadeh *et al.* (1994) found that strip intercropping had 20–24% higher maize yields and 10–15% lower soybean yields in adjacent border rows in Iowa, USA. In this case, the higher yield of border rows of the tallest species (maize) suggests increased radiation capture at the expense of the neighboring rows of the smaller species (soybean). In China, Li *et al.* (2001a) found that the yields in border rows of intercropped wheat were significantly higher than those in inner rows, in both wheat/maize and wheat/soybean intercropping systems. Waterworth (1994) suggested that a crop such as cotton, which both tolerates a wide range of population densities and has a late developing leaf canopy, may be particularly well suited to intercropping.

The greater yield in border rows can be attributed to greater LI (Zhang *et al.*, 2008a) and a better acquisition of nutrients in the border rows. The number of border rows is a major factor in determining the advantage of the productivity in intercropping systems. Li *et al.* (2001a) reported that yield increase of intercropped wheat is due to yield increase not only of border rows but also of inner rows in the wheat/maize intercropping systems.

An important aspect of an intercropping system is the extent of competition between the crops. The plant types of the intercropped species should be selected to complement each other (Smith and Francis, 1986; Davis and Woolley, 1993). Inadequate management of plant density can be detrimental to the intercrop (Davis and Garcia, 1987).

Below-Ground Interactions Between Species

Complementarity in Root Spatial and Temporal Distribution

Under field condition, crops in intercropping systems are not necessarily sown or harvested at the same time (Vandermeer, 1989). The growth rate and architecture of roots can differ greatly among different crop species, even if crops are grown and harvested at the same time. There are temporal and spatial niche complementarities in the use of resources, such as nutrients (Midmore, 1993; Morris and Garrity, 1993a, b; Stern, 1993; Li *et al.*, 2001a, 2003) and water (Sekiya and Yano, 2004). The niche complementarity hypothesis implies that plant species or functional groups occupy functionally distinct niches in an ecosystem and use resources in a complementary way (Kahmen *et al.*, 2006). Dynamics of temporal and spatial distribution of roots of different species in soil are directly related to nutrient acquisition and water capture in a mixture of different species. Therefore, the rooting patterns of mixed

species are related closely to the above-ground performance of these species in crop mixture.

The root spatial distribution between mixed crop species can be classified into three patterns:

1. Spatial separation of the crop root systems between the associated species, which results from interspecific interactions. Some species change the rooting pattern when associated with other species. For instance, sorghum distributes roots deeper in intercropping than in sole cropping, in which root distribution in spatial scale is separated from sunflower, a crop with a shallow rooting system (Miyazawa *et al.*, 2010). In an alley cropping system with *Acacia saligna* and *Sorghum bicolor* in northern Kenya, Lehmann *et al.* (1998) found that sorghum has more roots in the topsoil and the trees have more roots in the subsoil under alley cropping than in respective monoculture. As a result, the root system of the alley cropped *Acacia* and sorghum exploited a larger soil volume utilizing soil resources more efficiently than the respective monocultures (Lehmann *et al.*, 1998). By a means of ^{32}P tracer, Hauggaard-Nielsen *et al.* (2001) also found that interspecific interactions made the barley roots grow deeper and enhanced lateral root development in barley/pea intercropping, compared to sole barley cropping (Hauggaard-Nielsen *et al.*, 2001). By both auger and monolith methods, the root distributions were measured up to a depth of 100 cm in the soil profile in wheat (*Triticum aestivum*)/maize (*Z. mays*) intercropping and in sole wheat and maize cropping (Li *et al.*, 2006). Li *et al.* (2006) found that the roots of intercropped wheat spread under maize plants and had much greater root length density (RLD) at all soil depths than sole wheat, and the growth of maize roots was limited laterally by intercropped wheat (Li *et al.*, 2006), indicating that the root distribution of the two crops was changed by interspecific interactions.
2. The associated crops have inherently different traits in rooting patterns, with one being deeper and the other shallower in the soil profile. When grown together, interspecific competition is reduced, leading to overyielding. For example, *Crotalaria* (*Crotalaria juncea* L.) had a deep rooting system under both sole cropping and intercropping (Miyazawa *et al.*, 2010) that was not influenced by intercropping. The roots' separation in space decreased root competition, thus causing overyielding of above-ground parts compared to sole cropping.
3. Compatibility, or intermingling, between the roots of mixed crops facilitates resource utilization, thus overyielding. In faba bean/maize intercropping, for instance, interspecific interaction was mainly positive (or interspecific facilitation) (Li *et al.*, 1999). The roots of the two species were not distinctly separated from each other, and there was no apparent interspecific competition (Li *et al.*, 1999, 2006). The RLD of maize intercropped with faba bean at different soil depths was influenced by intercropping to a smaller extent, compared with maize intercropped with wheat. The roots of intercropped maize spread together with them (Li *et al.*, 2006). The intermingling of faba bean and maize roots in some zone enhanced nitrogen and phosphorus acquisition by crops

because faba bean roots are able to mobilize insoluble P in soil (Li *et al.*, 2007) and supply some N to maize (Fan *et al.*, 2006).

The temporal complementarity in root distribution in soil profile is another mechanism of crop mixture overyielding. There is some temporal differentiation in root development and growth between crop species because crops are not really sown and harvested simultaneously in many intercropping systems and because of the inherent traits of specific crop root growth. Using a ^{32}P labeling, Hauggaard-Nielsen *et al.* (2001) found that barley roots grow faster than pea roots, approximately 10 days earlier, in both vertical and lateral directions (Hauggaard-Nielsen *et al.*, 2001). In wheat/maize intercropping, the roots of intercropped wheat occupy larger below-ground space during the cogrowth stages of the two crops, compared to sole wheat cropping (Li *et al.*, 2006). After wheat harvesting, the roots of intercropped maize occupy the space under wheat and maize, which extends the maize to the below-ground space at a later growth stage (Li *et al.*, 2011). This explains the observed overyielding of intercropped maize with wheat (so-called recovery growth of maize after wheat harvesting (Li *et al.*, 2001b)). The temporal differentiation in root developments for wheat at an early stage and maize at a late stage partly explains the overyielding of wheat/maize intercropping in Gansu province, northwestern China.

Nitrogen Complementary Utilization in Legume-Based Crop Mixtures

Because nitrogen is an important limiting nutrient in arable soils, legume/cereal intercrops often overyield in tropical and temperate regions. Some of the symbiotic N_2 fixed by legumes is taken up by non N_2 -fixing species, increasing their growth and reducing nitrate leaching, which is aided by combinations of species with deeper and shallower roots. Nitrogen transfer from legumes to cereals occurs in most cases of intercropping legume-cereal systems. In a pot experiment, it was shown that N transferred from faba bean to wheat comprised 15% of the total N in wheat (Xiao *et al.*, 2004). Nitrogen transfer from peanut to associated aerobic rice was 11.4%, 6.4%, and 5.5% of the total N for rice in peanut/rice intercropping at N fertilizer application rates of 15, 75, and 150 kg N ha $^{-1}$, respectively (Chu *et al.*, 2004). Significant N transfer also occurs from sweet-blue lupine (*Lupinus angustifolius*) to Italian ryegrass (*Lolium multiflorum*) but not to intercropped westerwolde ryegrass (*L. multiflorum*) or oats (*A. sativa*) in intercropping systems (Palmason *et al.*, 1992). In maize-based intercropping, the proportion of N derived by maize from the associated legume varies from 7% to 11% for mungbean (*Vigna radiata*), 11–20% for cowpea (*V. unguiculata*), and 12–26% for peanut (*Arachis hypogaea*) (Senaratne *et al.*, 1995). In a soybean/sorghum intercropping system, approximately 7% of the total N accumulated by intercropped sorghum is transferred from the associated soybean (Ofosubudu *et al.*, 1993), whereas another study observed the proportion as 20–55% (Ofosubudu *et al.*, 1995). In contrast, nitrogen transfer does not occur from legumes to cereals in intercropping systems of cowpea/maize (Hardter and Horst, 1991), soybean/maize (Hamel *et al.*, 1991), field pea (*P. sativum*)/barley (Izaurrealde *et al.*, 1992; Jensen, 1996), mungbean/rice

(Aggarwal *et al.*, 1992), sweet-blue lupin (*L. angustifolius*)/oats (*A. sativa*) (Danso *et al.*, 1993), pea (*P. sativum*)/mustard (Waterer *et al.*, 1994), and cowpea/cotton (Rusinamhodzi *et al.*, 2006).

The occurrence of net nitrogen transfer depends on crop combinations (Fujita *et al.*, 1992; Farnham and George, 1993; Gebhart *et al.*, 1993; Stern, 1993; Farnham and George, 1994a, b, c; Cochran and Schlentner, 1995; Kobes and Simek, 1998; Beschow *et al.*, 2000; Carter and Ambus, 2006; Erkovan *et al.*, 2008; Serin and Erkovan, 2008). More specifically, it depends on the distance between legumes and cereals, because this affects the intermingling of roots (Ofosubudu *et al.*, 1993). Other factors include soil N concentration (Beschow *et al.*, 2000) and legume species (Stern, 1993).

Intercropping usually enhances the proportion of nitrogen derived from the atmosphere (%Ndfa) in the legumes, compared with that of corresponding legumes grown in monoculture. This occurs in sweet-blue lupin (*L. angustifolius*)/ryegrass (*L. multiflorum*) and sweet-blue lupin/oats (*A. sativa*) (Palmason *et al.*, 1992); cowpea (*V. unguiculata*)/maize, mung bean (*V. radiata* L.)/maize, and peanut (*A. hypogaea*)/maize (Senaratne *et al.*, 1995); vetch/barley (Kurdali *et al.*, 1996); dhaincha (*Sesbania aculeata*)/sorghum (*S. bicolor* L.) (Kurdali *et al.*, 2003); peanut/rice under 150 kg N ha $^{-1}$ of N fertilization, but not under lower rates of N-fertilizer application (Chu *et al.*, 2004); rape (*Brassica napus* L.)/pea (Andersen *et al.*, 2004); cotton (*Gossypium hirsutum*)/cowpea (*V. unguiculata*) (Rusinamhodzi *et al.*, 2006); wheat (*T. aestivum*)/faba bean (*V. faba*) (Fan *et al.*, 2006); and pea (*P. sativum*)/oat (*A. sativa*) intercropping (Neumann *et al.*, 2007). The amount of biological N_2 fixation by intercropped legumes is frequently reduced compared with that of legumes in monoculture, in line with a reduction of sown area or planting density for legumes in mixture. However, the amount of biological N_2 fixation increases by intercropping when expressed on the basis of equivalent land.

Cereals associated with legumes use more soil and N fertilizer through interspecific interactions. In a pot experiment of faba bean/wheat intercropping, fertilizer ^{15}N was added to soil. The amount of N derived from ^{15}N added to soil of wheat was 24, 30, and 43 mg per pot in the treatment without root interactions (due to a solid barrier), with mesh barrier (partial roots interactions), and without barrier (complete root interactions), respectively (Xiao *et al.*, 2004). The root contact enhanced ^{15}N acquisition of wheat, but decreased that of faba bean.

These results indicate that interspecific interactions between legumes and cereals made cereals acquire more soil N, which forced the legumes to fix more nitrogen from air.

Reduced nitrogen leaching in the soil profile could play a role in determining nitrogen-acquisition efficiency of the intercropping system. Nitrogen leached from the root zone of N_2 -fixing plant could be taken up by nearby roots of non N_2 -fixing plants. For instance, nitrate leaching tended to be smaller in the lysimeters originally cropped with pea–barley intercrops than in those of sole pea crop (Hauggaard-Nielsen *et al.*, 2003). In a maize/soybean intercropping system, maize grain yields were increased by 5% and $\text{NO}_3\text{-N}$ leaching losses reduced by 6% (Kanwar *et al.*, 2005). A study of an oat/pea mixture showed that oat in mixture acquired more soil N from

deeper layers. Therefore, the risk of soil N losses through leaching after mixtures can be lower than that after a monoculture of pea (Neumann *et al.*, 2007).

In Africa, *Faidherbia albida*, a legume tree species, can increase yields of associated crops when they are intercropped together. Garrity *et al.* (2010) reviewed research conducted in various countries on the improvement of soil nutrient content and crop yields under *F. albida* canopies, compared with controls in the open. Increases in nitrogen content ranged from 15% to 156%, but significant increases were also found in carbon, phosphorus, exchangeable potassium, calcium, and magnesium in soil. As a result, increases in millet yields ranged from 49% to 153% and in sorghum from 36% to 169%. In absolute terms, this means, in most cases, an additional cereal yield of 400–500 kg ha⁻¹ or more. Yield increases of 37% were observed for groundnut, 200% for sorghum in the north-central Senegal, and 115% for sorghum in Burkina Faso (Garrity *et al.*, 2010).

Phosphorus Facilitation Between P-Efficient Species and P-Inefficient Species

Although plants often perform poorly on soils with low levels of soluble P, some of these soils contain considerable reserves of P that is unavailable to most species, such as sparingly soluble inorganic P and organic P in soil. There is significant difference in P acquisition from soil between different plant species. P-efficient species usually acquire insoluble soil P or organic P much more than P-inefficient species do.

Phosphorus acquisition of P-inefficient species may benefit from the presence of P-efficient species when they grow close together. Interspecific facilitation of P acquisition for wheat (*T. aestivum*)/white lupine (*Lupinus albus*) (Horst and Waschkies, 1987), sorghum (*S. bicolor*)/pigeon pea (*C. cajan*) (Ae *et al.*, 1990), wheat (*T. aestivum*)/chickpea (*Cicer arietinum*) (Li *et al.*, 2003), peanut (*A. hypogaea*)/maize (*Z. mays*) (El Dessougi *et al.*, 2003), and maize (*Z. mays*)/chickpea (*C. arietinum*) (Li *et al.*, 2004) intercropping has been observed in greenhouse pot experiments, and for faba bean (*V. faba*)/maize (*Z. mays*) intercropping under field conditions has been observed (Li *et al.*, 2007). The mechanisms underlying interspecific facilitation include efficient acquisition of organic P (Li *et al.*, 2003, 2004) and poorly available inorganic P (Horst and Waschkies, 1987; Ae *et al.*, 1990; Li *et al.*, 2007) by P-efficient species, which enhances P acquisition of P-inefficient species in intercropping systems.

Faba bean (*V. faba*) facilitated P acquisition of associated maize (*Z. mays*) under both field and greenhouse conditions. Overyielding was an average 46% for maize and an average 26% for faba bean in a 4-year field intercropping experiment; intercropping enhanced P acquisition by faba bean and maize, compared with that by the respective species in monoculture (Li *et al.*, 2007). There is temporal and spatial niche differentiation in resource acquisition for these species, with faba bean being sown and harvested earlier than maize under traditional farming practices. Greenhouse experiments have shown interspecific facilitation between faba bean and maize in terms of P acquisition and growth when temporal and spatial niche complementarity are diminished by sowing both at the same time and when their roots exploit the same soil volume (Li *et al.*, 2007). The physiological mechanism

involved in this facilitation is that faba bean acidifies the rhizosphere by releasing protons and mobilizing insoluble soil P by exuding malate and citrate (Li *et al.*, 2007), which are chelating agents that mobilize P bound to calcium in calcareous soil and solubilize phosphate sorbed to soil particles (Hinsinger, 2001). Crop species vary widely in their capacity to access sparingly soluble inorganic P (Pearse *et al.*, 2006). Therefore, the combination of P-efficient and P-inefficient species is able to overyield under P-deficient soils.

Chickpea (*C. arietinum*), a species that effectively accesses organic P, facilitates P acquisition by associated organic P-inefficient wheat (*T. aestivum*) (Li *et al.*, 2003) and maize (*Z. mays*) (Li *et al.*, 2004) when grown in intercropping systems. The physiological mechanism behind this facilitation is the exudation from roots of chickpea of acid phosphatases (Li *et al.*, 2004), which hydrolyze organic P (Li *et al.*, 1997) and benefit both species when growing together. Many crop species (e.g., *L. albus* and *Trifolium subterraneum*) can access nucleic acids, phospholipids, glucose-1-phosphate, and glycerophosphate in soil, due to the release of phosphatases from their roots (Lambers *et al.*, 2008). This may be an important mechanism of facilitation and overyielding in P-limited soils.

Fe/Zn improvement In Mixture

Some iron-inefficient species, for example, guava (*Psidium guajava*), peanut (*A. hypogaea*), and red fescue (*Festuca rubra*) frequently show iron chlorosis when growing in calcareous soils (Kamal *et al.*, 2000; Zuo *et al.*, 2000; Ma, 2005). The condition can be improved greatly by intercropping these plants with Fe-efficient graminaceous species (Kamal *et al.*, 2000; Zuo *et al.*, 2000; Inal *et al.*, 2007). Greenhouse rhizobox studies demonstrated that the Fe nutrition of peanut or guava intercropped with maize was mainly improved by rhizosphere interactions between peanut or guava and maize (Kamal *et al.*, 2000; Zuo *et al.*, 2000). When peanut and maize grow together, phytosiderophores released by maize roots mobilize Fe(III), which may then diffuse from close to the roots of maize to the root surface of peanuts. At the root surface of peanuts, Fe(III) can be reduced, and thus the release of phytosiderophores from maize roots may improve the iron nutrition of Fe-inefficient plants. Intercropping increases Zn extractability in calcareous soils and the Zn content in guava leaves (Kamal *et al.*, 2000). Similar results have been obtained for the peanut/maize intercropping system, increasing both Fe and Zn acquisition (Inal *et al.*, 2007).

Water

Increased water capture, or water use (WU): Water capture (evapotranspiration) was increased to 604–609 mm in wheat/soybean relay intercropping from 313 to 334 mm for sole wheat and 434 to 359 mm for sole soybean in the south-eastern Pampas. The relay intercropping used a much larger fraction of annual precipitation than sole crops, the fraction increased from 0.26 to 0.51 in sole crops and from 0.53 to 0.71 in the wheat/soybean relay intercropping (Caviglia *et al.*, 2004). The crop coefficient K_c , an important item for evaluating crop evapotranspiration, is defined as the ratio of actual crop evapotranspiration to reference crop evapotranspiration. The K_c in winter wheat/spring maize strip intercropping was slightly higher than that in the monocultures because the

evapotranspiration in the intercropping system was higher than that in monocultures (Gao *et al.*, 2009). However, even though some other crop treatments used water differently within the soil profile, there were no differences in WU between spring wheat sole crop, canola sole crop, field pea sole crop, wheat/canola intercropping, wheat/pea intercropping, canola/pea intercropping, and wheat/canola/pea intercropping (Szumigalski and van Acker, 2008).

Water use efficiency (WUE): The ratio of yield or biomass to WU differed with crop combination. Some crop combination enhanced WUE, but some did not. Maize/beans intercropping had WUE as high as maize sole cropping, and intercropping WUE were greater than bean sole cropping in a semiarid region of South Africa (Tsubo *et al.*, 2003). Greater WUE in the intercrop system was attributed to differences in canopy structure and plant biomass production. Faba bean and red fescue had lower WUE than barley and the intercrop (Izaurrealde *et al.*, 1994). The combination with *A. saligna* and *S. bicolor* in northern Kenya used the soil water from between hedgerows more efficiently than the sole cropped trees or crops, as water uptake of the trees reached deeper and started earlier after flood irrigation than for sorghum, whereas sorghum better utilized topsoil water (Lehmann *et al.*, 1998). Under the experimental conditions, the root system of alley cropped Acacia and sorghum exploited a larger soil volume and utilized soil resources more efficiently than the respective monocultures (Lehmann *et al.*, 1998).

However, in a 5-year-study in Loess Plateau with sole switchgrass, milkvetch, and switchgrass/milkvetch intercropping, Xu *et al.* (2008) found that WUE in both sole switchgrass and milkvetch was greater than that in switchgrass/milkvetch intercropping ($p < .05$) across an average of 5 years (Xu *et al.*, 2008). In a study of intercropping of wheat, canola, and field pea in Manitoba, Canada, the WUE was not different from that in sole cropping. The overyielding in intercrops was inconsistent and seemed to be related more to LI than to water utilization (Szumigalski and van Acker, 2008). Average WUE in winter wheat/spring maize intercropping system in the Huang-Huai-Hai Plain of China was $21.72 \text{ kg ha}^{-1} \text{ mm}^{-1}$, which was 23% less than that of the sole maize, but 4% greater than that of the sole wheat. Therefore, although winter wheat/spring maize intercropping system does not improve WUE, it may significantly raise yield (Gao *et al.*, 2009).

Hydraulic lift effect: During periods of drought, water may be transported upward through root systems from moister subsurface to dry surface soil by a process known as 'hydraulic lift.' On warm and dry days when plant transpiration peaks, hydraulically lifted water released into soil can support growth and survival of the lifting and neighboring plants. Soil and rhizosphere microorganisms and the soil fauna could also benefit from hydraulic lift-derived water, which eventually increases the availability of nutrients to plants. Although hydraulic lift was examined mainly in the context of terrestrial plant ecology, this biological subterranean sprinkler process may also prove to be a sustainable alternative to conventional engineered irrigation techniques currently used for agronomical purposes (Liste and White, 2008). Introduction of deep-rooted species into intercropping systems can allow shallow-rooted crops to utilize otherwise unavailable water sources deep in the soil layers. Sekiya and Yano (2004) found that pigeon pea

supplied water from deeper soil layers to the associated maize plants through hydraulic lift, whereas sesbania did not. The interspecific difference in the sprinkler-like function of hydraulic lift could be attributable to the differences in root structures between the two legumes (Sekiya and Yano, 2004).

Symbiosis with Mycorrhiza

Vesicular-arbuscular mycorrhizal (VAM) fungi interconnect the root systems of adjacent plants and probably mediate the transfer of nutrients between different plant species. In a mixture of wheat and ryegrass, wheat growth and yield were enhanced and ryegrass growth was inhibited in +VAM herbicide-treated associations (Rejon *et al.*, 1997), which was reversal of sole crops. Rejon *et al.* (1997) explained that wheat, as a stronger sink, was interconnected to associated ryegrass via VAM mycelium between two species; nutrients were transferred from ryegrass roots to wheat by the VAM mycelium (Rejon *et al.*, 1997).

Crop Pest and Disease Control

Crops in mixture are often less damaged by pest and disease organisms than when grown as sole crops (Trenbath, 1993), which is an additional mechanism underlying overyielding.

Push–Pull Principle and Biological Pest Control

Push–pull strategies use a combination of behavior-modifying stimuli to manipulate the distribution and abundance of pest and beneficial insects for pest management. Strategies targeted against pests try to reduce their abundance on the protected resource, for example, a crop or farm animal. The pests are repelled or deterred away from this resource (push) using stimuli that mask host apparency or are repellent or deterrent. The pests are simultaneously attracted (pull), using highly apparent and attractive stimuli, to other areas such as traps or trap crops where they are concentrated, facilitating their elimination (Cook *et al.*, 2007). For instance, intercropping cauliflower with noncrucifer host plants, like sunflower (*H. annuus* L.), marigold (*Tagetes erecta* L.), tomato (*L. esculentum* L.), lucerne (*Medicago sativa* L.), and berseem (*T. alexandrinum* L.), significantly reduced aphid, larvae of diamond back moth and cabbage butterfly incidence and had more numbers of aphidivorous coccinellids, a larval parasitoid. As a result, higher yield in intercropping was observed than in the sole crop of cauliflower (Muthukumar and Sharma, 2009).

Genetic Diversity Controls Crop Disease and Improves Lodging-Resistance

Genetic diversity of crop in mixture controls disease through supporting diverse pathogens. Hybrid and glutinous rice intercropping has been popular and has become more and more important in modern agriculture in the Yunnan Province of China, due to its control of rice blast, a serious disease for rice. Zhu *et al.* (2000) found that disease-susceptible rice varieties, glutinous rice, planted in mixtures with resistant varieties, hybrid rice, had 89% greater yield and blast was 94% less severe than when they were grown in monoculture (Zhu *et al.*, 2000). By polymerase chain reaction (PCR) fingerprinting of pathogen, the genetic composition of the pathogen populations

derived from intercropping and monoculture was determined, and results indicated that the mixtures supported diverse pathogen populations with no single dominant strain. In contrast, pathogen populations from monoculture were dominated by one or a few strains (Zhu *et al.*, 2000). The more diverse pathogen population from the mixed stands may have contributed to greater induced resistance from incompatible interactions (Zhu *et al.*, 2000). Recent results in the system showed that prevention of lodging of the tall glutinous rice was identified as an important additional advantage of growing these rice varieties in mixture as a consequence of the presence of the lodging-resistant hybrid rice (Revilla-Molina *et al.*, 2009).

Species Diversity Controls Crop Disease

In common bean-based intercropping systems, the mean bean rust incidence and severity were reduced by 25% and 16%, respectively, compared with sole cropping. Similarly, bacterial blight incidence was reduced by 29% and severity by 20% (Fininsa and Yuen, 2001), which probably resulted from a slower disease progress rate on beans planted with maize or sorghum in row, mixed, and broadcast intercropping than on bean planted alone (Fininsa and Yuen, 2002). Consequently, overyielding in common bean intercropped with maize or sorghum was observed (Fininsa, 2003). As large as 20% of annual yield losses resulted from leaf spot diseases caused by various pathogens, including the septoria leaf spot complex consisting of *Septoria tritici* Roberge in Desmaz. and *Stagnospora nodorum* (Berk.) Castellani & E. G. Germano, which cause septoria and stagnospora blotch, respectively, and *Pyrenophora tritici-repentis* (Died.) Drechs., which causes tan spot (Hummel *et al.*, 2009). Hummel *et al.* (2009) suggest that wheat disease severity in canola/wheat intercropping decreased with increasing canola proportion, suggesting a possible interference of the canola on the infection of wheat plants (Hummel *et al.*, 2009). At the same time, wheat/canola canopies, which enclosed the interrows and maintained higher humidity, may have exacerbated wheat leaf disease infestations compared to those in monocultures (Hummel *et al.*, 2009).

Large-scale intercropping experiments in 15,302 ha of farmland in Yunnan Province of China have provided evidence that intercropping had significant yield advantages in tobacco/maize, sugarcane/maize, potato/maize, and wheat/faba bean intercropping systems and protected intercropped crops from various diseases (Li *et al.*, 2009). The severity of northern maize leaf blight in intercropped plots was decreased by 17.0% and 19.7% in 2006 and 2007, respectively, compared with the sole plots, although tobacco brown leaf spot disease in intercropping and sole cropping was comparable. The severity of sugarcane eye spot disease was comparable in sole and intercropped sugarcane with maize, but northern maize leaf blight in intercropped plots decreased by 55.9% and 49.6% in 2006 and 2007, respectively, compared with the sole cropping. Severity of potato late blight in the intercropping system was decreased by 32.9% and 39.4% in 2004 and 2005, respectively, compared to corresponding sole potato; simultaneously northern maize leaf blight in intercropped plots was decreased by 30.4% and 23.1%. The severity of broad bean chocolate spot disease in the intercrops also decreased by 33.8% and 31.7% in 2004 and 2005, respectively, compared with sole faba bean (Li *et al.*, 2009). The reduced

disease severity in maize was associated with less rainfall during the earlier growing period of the intercropped maize with sugarcane, and that in faba bean with reduced disease spread among faba bean plants because they were separated by rows of wheat plants (Li *et al.*, 2009).

Conclusions

Overyielding of crop mixtures was frequently observed with various combinations of crops all over the world. The mechanisms underlying the overyielding are attributed to both above-ground and below-ground interspecific interactions between crop species. Above-ground interactions include increased LI complementarity across temporal and spatial scales. Below-ground interspecific interactions involve reduction of competition by temporal and spatial differentiation in the distribution of the roots of mixed crops and enhanced nutrient (nitrogen, phosphorus, and some microelements) acquisition by interspecific facilitation. In some but not all cases, a similar enhancement of water capture and water use was observed in crop mixtures. Finally, crop mixtures may enhance genetic and species diversity in agroecosystems in ways that help control crop pests and disease.

There is little information on long-term changes in soil fertility under crop mixture, which is a key factor for sustainability of the cropping systems, because overyielding results in more nutrient and water consumption in crop mixture. Crop mixture, with two or more species, adds some complexity of research; therefore, it is important in future study to employ simulation models as tools to determine the dynamic processes of interspecific interactions in the systems.

Glossary

Cultivated plants Plants that are grown for their produce.

Self pollination The pollination of a flower by pollen from the same flower or from another flower on the same plant.

Vegetative reproduction (vegetative propagation, vegetative multiplication, vegetative cloning) Is a form of asexual reproduction in plants. It is a process by which new individuals arise without production of seeds or spores.

Introduction

The original focus of farming was on growing food crops; but this was soon extended to include plants essential for other utilities such as fiber sources, stimulants, medicinal aids, dye crops, forage, and timber production. In addition, the past two or three centuries witnessed another major development, namely a massive introduction of ornamental plant species into cultivation. (Today the number of ornamental species exceeds the number of food crops.) Most recently, plants with medicinal properties are getting new attention. The potentials of scores of such plant species (traditionally collected from the wild) have been evaluated. To ensure a steady supply, and for improving quality and yields, many of them are presently introduced into cultivation. A parallel trend is apparent in forestry. Here, too, dozens of timber producing trees are being quickly domesticated. To date, thousands of plant species, native to the various phytogeographic regions of the World, have been introduced into cultivation. In the majority of these cases, the domestic derivatives have already been drastically altered by this move. So much so that the cultivated forms can no more survive in the wild and have become dependent on humans for their existence. Grain crops, for example, lost the wild type adaptation to disperse their seeds and depend on the harvesting, threshing, and sowing by the farmer. Vegetatively propagated tuber plants (under domestication) are commonly sterile. So are many seedless varieties of fruit crops (e.g., bananas). Moreover, as a result of (a) the ecological shift from the original wild habitats into the greatly different and varied anthropogenic environments and (b) repeated cycles of deliberate selection by humans, many domesticates have greatly diverged under domestication. In most major food crops (e.g., bread wheat, rice, maize, apple, or grapevine) or in many popular ornamentals (e.g., roses, rhododendrons, narcissi, tulips, irises), hundreds or even thousands of distinct cultivated varieties ("cultivars") or ornamental forms are now recognized, fitting the wide range of conditions under which these plants are being maintained and the different and contrasting wishes of the growers who constantly try to improve their plants by selection. All in all, domestication provides us with most impressive examples of rapid evolution in plants. Vast arrays of morphological, anatomical, physiological, and chemical changes have evolved in crops and ornamentals, and

this in a very short span of evolutionary time. Moreover, selection under domestication molded the gene pools of the crops (the "cultivated gene pools") to become the backbone for the production of food and other essential utilities for humankind. Today, our very existence depends on this genetic diversity. Thus not only do the crops become dependent on humans; also humans became dependent on crops. Obviously, civilizations and domesticated plants have coevolved; and this coevolution continues today.

The Traditional Agricultural Systems of the World

In classical times (about 2500–2000 years ago), and to a large extent until Columbus's time, agriculture was structured quite differently from what we find it today. At present, each country grows a mixture of crops introduced from the various parts of the world. But this fusion is very recent. Traditionally, farming was practiced in largely separated, independent regions, each occupying extensive territories and each possessing a characteristic and largely unique ensemble of native crops. When the Europeans discovered America, they found that the flourishing agricultural civilizations in the New World were based on growing crops that were totally different from what they were familiar with in Eurasia and in Africa. The two hemispheres are indeed very rich in cereals, pulses, tubers, fruits, vegetables, spices, and other types of cultivated plants. Yet the list of domesticated plants in each of them is unique. With only one or two exceptions, these two landmasses originally had no crops in common. This strongly indicates that domestication and agriculture in each of them evolved independently.

Also within each of the two hemispheres, one can detect similar patterns. Each landmass seems to contain several historical agricultural regions, previously separated by difficult-to-cross geographic and cultural barriers. Thus the crops of the traditional agriculture system in Southwest Asia, the Mediterranean basin, and temperate Europe were very different from those grown in East Asia. Moreover, the crop composition in each one of these two agricultural systems is very different from the crop assemblage in Africa south of the Sahara. Similarly in the New World, numerous crops grown in South America were not known in Mexico and middle America, and vice versa.

The main food crops in the traditional agricultural regions of the world are given in Appendix 1. A comparison between the various regional lists of crops reveals that each agricultural system usually contains dominant cereals, companion pulses, oil plants, fruit crops, vegetables, spices, tubers and corms, and stimulants. In other words, the composition of crop *kinds* repeats itself. Only the plant species are different in each traditional region (for example, wheats and barley, lentil, and pea in Southwest Asia, the Mediterranean basin, and Europe; rice and soybean in East Asia; maize and *Phaseolus* beans in America; and sorghum and other millets and cowpea in Africa south of the Sahara).

The Emergence of Agriculture

The shift from hunting and gathering to farming started relatively very late in the history of *Homo sapiens*. The archaeological and botanical evidence already assembled on this development is not even. Some parts of the world (the Mediterranean basin, the Nile Valley, temperate Europe, Southwest Asia, North America) have already been extensively studied. Other parts of the world (East Asia, the Indian subcontinent, South America) are much less explored but at least provide us with some critical evidence on the beginning of agriculture in them. In still others (Africa south of the Sahara, most of the tropical parts of the world) archaeobotanical information is still very poor or almost nonexistent. Even so, the available information clearly shows that farming was independently initiated in several geographically and culturally separated “nuclear areas,” both in the Old World and in the New World, between 10,000 and 5,000 years before present (B.P.). uncalibrated radiocarbon time.¹ In each such area cultivation seems to have been independently invented, and native wild plant species—largely unique to each area—were introduced and tested in cultivation. Some evolved to be the “founder crops” that initiated farming in these independent places. Once this new way of life had been successfully established, these domesticates also formed the basis for a territorial expansion of the newly formed agricultural populations and for further development in food production.

The First Old World Territory

The oldest and the most extensively studied nuclear area is the “fertile crescent” belt of the Near East. In this rather small geographic territory, a string of early Neolithic farming villages started to appear some 9500 years ago and further established themselves in the subsequent 1500 years. Plant remains retrieved from these early archaeological sites show that eight grain plants growing wild in this Near Eastern “arc” were domesticated at these times. Most common in these pre-ceramic Neolithic Near Eastern sites were remains of three

cereals: emmer wheat, einkorn wheat, and barley. They were accompanied by pulses (lentil, pea, chickpea, bitter vetch) and by flax. Soon later, by 8500–8000 B.P., signs of domestication of sheep, goat, cattle, and swine appeared in the sites as well, and the Near Eastern “package” for food production was formed.

Once the package was assembled, and the early Neolithic farming villages were soundly established, farmers started to expand. They did so explosively. By 8000 B.P. this type of agriculture was already introduced into Greece, and by 7000 B.P. it had reached the Danubian basin, the Nile Valley, the Caucasus, and Turkmenistan, and soon afterward it was introduced in the Indus basin. By 6500 to 6000 B.P., grain crop agriculture (and cattle and caprine rearing) was already established all over major parts of temperate Europe—from Ukraine in the east to northern France in the west. More or less at the same time, this new technology also appeared in the middle and western parts of the Mediterranean basin as far as south Spain. All over these vast territories of Southwest Asia, the Nile Valley, the Mediterranean basin, and temperate Europe, agriculture was started by the introduction of the same Near Eastern crops (wheats and barley, and their companion pulses and flax). Only later were additional plants, native to other parts of this huge region, added (e.g., poppy *Papaver somniferum*) in the west Mediterranean basin.

Some 3000 years after the start of Neolithic grain agriculture, fruit crop horticulture (based on the invention of vegetative propagation) appeared in this region. As with grain crops, the earliest convincing signs of fruit tree cultivation were found in the Near East. Olive, fig, grapevine, and date palm have been cultivated here at least since Chalcolithic times (5500 B.P.). Horticulture, too, spread quickly. By the late Bronze Age, olive, grapevine, and fig (as well as pomegranate and almond) were already used as principal elements of food production in the Aegean belt; and date palm groves flourished in the warm fringes of the Near East and the eastern Mediterranean basin (including Egypt) and extended eastward as far as the Indus Valley.

From the Bronze Age onward there are sound indications of cultivation of vegetables. Melon, watermelon, onion, garlic, leek, and lettuce were the first vegetable crops grown in Mesopotamia or in Egypt. Definite signs of their cultivation appear by 4500 to 3500 B.P. By 2800 to 2000 B.P., the list of Mediterranean and Southwestern Asian vegetable crops had grown considerably; and beet, turnip, cabbage, radish, carrot, parsnip, celery, parsley, and asparagus had also entered cultivation. More or less at the same period (2400–2000 B.P.), a second group of native fruit trees (those in which cultivation depends on grafting) was also added. Most conspicuous among them are apple, pear, plum, and cherries. Contrary to the earlier crops that were almost all taken into cultivation in the Near East “arc,” many of the vegetables and the late fruit trees were probably picked up for domestication, not in the Near Eastern nuclear area but in other parts of the already vast Mediterranean and Southwest Asian system of agriculture. Thus, starting in the Neolithic and ending in classical times, an impressive assemblage of native crops were domesticated and diffused all over Southwest Asia, the Mediterranean basin, and temperate Europe. Most of them remained economically important until today.

¹Uncalibrated radiocarbon ¹⁴C years are used throughout this chapter and expressed as years before present (B.P.). Note that dendrological (tree rings) calibration adds to these values—more to the older dates, less to the younger ones. For early ¹⁴C dates (9000–5000 B.P.), the correction adds some 700 to 1000 years. By 3000 B.P. radiocarbon time, the differences are negligible.

The Second Old World Territory

A second Asian nuclear area—or more exactly two closely situated, but independent initiations of farming—have been discovered in East Asia. The first was uncovered in the loess soil belt in Honan province and adjacent areas, in the middle part of the Yellow River Valley in North China. The second in the Hupei basin in Central China, along the middle Yangtze River, and also in the wetlands of its delta. The evidence available on the start and on the subsequent development of agriculture in China is still fragmentary compared to that available on the Near East. Yet very ancient farming villages have been discovered both in the northern and in the central parts of this large country. They represent the oldest undisputed signs of plant domestication found yet in East and in South East Asia.

In the Yellow River Valley the oldest farming sites date from 8000 to 7000 B.P. and they contain very large amounts of foxtail millet, indicating that in temperate North China this cereal had been the principal founder crop of the local agriculture. Also in later times foxtail millet continues to be a major food crop in China. More or less in the same time, farming villages seem to have appeared in the middle of the Yangtze River Valley. The earliest sites discovered there date even somewhat older (8500–7000 B.P.) than those in north China. Significantly, in these sites the dominant crop is rice, which later emerges as the most important crop of the vast agricultural economies of East and Southeast Asia. Massive remains of this cereal were unearthed in the Hupei basin, and they continue to appear in the Yangtze River Valley and in later archaeological contexts. These are the oldest remains of rice found yet. But because they occur on the fringe of the wild rice distribution area, some workers suspect that even older rice sites will be discovered in the future further south.

The Third Old World Territory

A third territory in the Old World suspected to have had an independent initiation of agriculture is the Savanna belt and its forest margin in Africa south of the Sahara. The traditional agriculture in this region (which stretches from Senegal and Guinea to Sudan) is based, almost entirely, on a rich assemblage of native crops such as sorghum, pearl millet, African rice, fonio, cow-pea, and bambara groundnut (Appendix 1). The highlands of Ethiopia border the Savanna belt in the east and also harbor an impressive list of local crops, such as teff, finger millet, coffee, and noog. But here the African plants grow side by side with wheat, barley, and many other Near Eastern elements that reached Ethiopia in the past. All in all, African agriculture is diverse and adapted to a wide range of situations. Apart from the Near Eastern elements in Ethiopia, its rich crop assemblage seems almost fully indigenous. This is borne by the fact that the wild relatives of the crops are restricted in their distribution to this part of the World. Most of them could have been introduced into cultivation only somewhere in this geographic belt. All this seems to suggest the independent initiation of cultivation. Whether this is indeed the case is yet hard to say. Archaeologically, Africa south of

the Sahara is practically unexplored. The few data available on cultivation of pearl millet or other crops are no more than 3000 years old.

The American Territory

There is little doubt that farming was independently invented in the Americas. As already noted, in pre-Columbus times the Eastern hemisphere and the Western hemisphere shared almost no crop in common. On basis of this evidence it is hard to imagine agricultural contacts between the two landmasses before that time. Also in America itself archaeological research has revealed definite signs of early cultivation, not in a single area but in several distantly located places.

Relatively early rich finds (the age of which has been recently corrected by direct ^{14}C accelerator mass spectrometry tests to 4700 B.P. onward) were discovered in several caves and rock shelters in central and SW Mexico. They contain numerous remains of what are clearly primitive cultivated maize forms, as well as common bean and squash. Because the wild progenitor race of maize—the principal crop in this triad—is restricted only to this general area, it seems reasonable to regard southwestern Mexico as a nuclear area where maize (and its two accompanying crops) were taken into cultivation. This crop combination also remained the main source for food production in the Aztec days.

Indications of early, possibly independent initiation of cultivation come from South America. Chemical comparisons have shown that the common bean and lima bean were independently domesticated both in middle and in South America. Finds in the central and south Andes show that potato and Quinoa cultivation in these elevated areas might be 5000 years old, although dating is yet problematic. Finally, sound evidence has been assembled that independent domestication of plants took place in eastern North America. Here goosefoot *Chenopodium berlandieri*, sunflower, and marsh elders were cultivated at least 4000 to 3500 years ago. This is some 2000 years before maize or any other outsider crop reached this area.

Reproductive Systems in Plants Under Domestication

Cultivated plants differ markedly from wild plants in the way by which they are reproduced and maintained. In the various families of the flowering plants, cross-pollination is the principle genetic system. Most species build out-breeding populations. Other reproductive systems such as self-pollination and vegetative propagation (including apomixis) occur as well and are even common in some genera and families. Yet compared to sexual reproduction by cross-pollination, their overall weight is small. In contrast, cross-pollination is relatively rare in plants under domestication. Most crops are maintained by one of the following two systems: (a) self-pollination and (b) vegetative propagation. In contrast to cross-pollination, both these reproductive systems are effective in bringing about immediate “fixation” of desired genotypes.

Self-Pollination

Self-pollination, or more exactly almost full self-pollination, is the principle mating system found in grain crops and in many vegetables. The majority of the 50–60 main grain crops of the world are predominantly self-pollinated. Only a few (such as maize, rye, pearl millet, buckwheat, or scarlet runner bean) are cross-pollinated. Now that the wild progenitors of the majority of the grain crops are already satisfactorily identified, we know that the wild ancestors of the self-pollinated crops are also self-pollinated. In other words, self-pollination in grain crops did not evolve under domestication. It is rather a “pre-adaptation” of the wild ancestor, which considerably enhances its chance to perform successfully in cultivation. One major advantage of self- over cross-pollination is the fact that self-pollination isolates the crop reproductively from its wild progenitor. It enables the farmer to grow a desired genotype in the same area in which the wild relatives abound without endangering the identity of the cultivar by genetic swamping. A second advantage of self-pollination lies in the genetic structure maintained within the crop. Self-pollination results in splitting the crop’s gene-pool into independent homozygous lines. Variation is thus structured in the form of numerous true breeding cultivars. Because they are automatically “fixed” by the pollination system, they can be easily maintained by the farmer, even if they are planted together. In contrast, the preservation of varietal identity in cross-pollinated plants is much more problematic. It requires repeated selection towards the desired norms, constant care to avoid the mixing of types and the prevention of contamination from undesirable plants. It is therefore not surprising that early successes in plant domestication frequently involved selfers. In fact, all the eight Neolithic Near Eastern founder crops have this system of reproduction.

Vegetative Propagation

Vegetative propagation is the second widely adapted means to fix and maintain desired genotypes under domestication. This way of handling prevails in the fruit trees, in tuber and corn crops, and in numerous ornamentals. Here, domestication means first of all changing the reproductive biology of the plants involved by shifting from sexual reproduction (in the wild) to vegetative propagation (under cultivation). As a rule, cultivated varieties of these plants have been maintained as clones by cuttings, rooting of twigs, suckers, or by the more sophisticated technique of grafting (and recently also by meristem tissue culture propagation). This is in sharp contrast with their wild progenitors, which reproduce from seeds. Their wild growing populations are usually variable, maintain themselves through sexual reproduction, and are distinctly cross-pollinated. Consequently, seedlings raised from any mother plant segregates widely in numerous traits, including the size, shape, and palatability of the fruits or the tubers.

In the hands of the grower, vegetative propagation has been a powerful device to prevent genetic segregation and to “fix” desired genotypes. By discarding sexual reproduction and inventing clonal propagation, the farmer was able to select, in a single act, exceptional individuals with desirable

traits from among a large numbers of variable, inferior plants. Moreover, the farmer could duplicate the chosen types to obtain genetically identical saplings. This is no small achievement. Because the plants are cross-pollinated and widely heterozygous, most progeny obtained from them (even from “superior” plants) are economically worthless. The change from seed planting to vegetative propagation has been a practical solution to assure a dependable supply of desired genotypes. In most fruit trees—and in many tuber crops and ornamentals—it made domestication possible. The history of the Mediterranean fruit trees illustrates this clearly. Olive, grapevine, fig, and date palm that can be relatively simply cloned (by twig rooting or by suckers) were the first to enter cultivation (already by 5500 B.P.). Other native fruit trees that do not lend themselves to easy rooting (e.g., apple, pear, plum, cherry) were domesticated much later (about 2400–2000 B.P.). Their incorporation into horticulture became possible only after the invention of a new cloning tool, namely scion grafting.

Conscious Versus Unconscious Selection

Two main types of selection operate (and complement each other) in plants under domestication:

1. Conscious selection deliberately applied by the growers for traits of interest to them.
2. Unconscious selection brought about by the fact that the plants concerned were picked up and isolated from their original wild environment and placed in a new (and usually very different) human-made environment. This shift in the ecology led automatically to drastic changes in selection pressures. In response to the introduction of the plants into the anthropogenic environment, numerous adaptations vital for survival in the wild lost their fitness. New sets of traits were automatically selected for to fit the new conditions, resulting in the buildup of characteristic domestic adaptations and the appearance of “domestication syndromes”—each fitting the specific agricultural system provided by the domesticators.

Although the pressures and the effects of conscious selection in shaping domesticated plants are familiar to both plant breeders and crop plant evolutionists, unconscious selection has been less frequently evaluated. Because this type of selection shapes so many of the principal traits that characterize crops, several developments caused by the shift in the ecology are discussed in some detail in the following sections.

Methods of Maintenance of Crops and their Impact

As already noted, two main methods of maintenance are employed by the cultivators to maintain their crops: (a) planting of seeds and (b) vegetative propagation. The choice between these two agronomic practices is also the choice between two contrasting patterns of selection and modes of evolution under domestication.

With very few exceptions of apomixis (such as nucellar seed in citrus fruits and mango) planting of seeds can be equated with sexual reproduction. Cultivated plants maintained by seeds (the bulk of the grain crops, numerous vegetables and forest trees, some ornamentals) therefore undergo a recombination-and-selection cycle every planting. In other words, such crops had, under domestication, hundreds or even thousands of generations of selection. They have been continually molded either as (a) clusters of inbred lines (in predominantly self-pollinated crops) or as (b) distinct cultivated races (in cross-pollinated plants). In numerous sexually reproducing crops, the results of such repeated selection are indeed striking. Under domestication these crops have diverged considerably from their wild progenitors. They are now distinguished from them by numerous morphological, developmental, physiological, and chemical traits.

Crops maintained by vegetative propagation (most fruit trees and tuber crops, few vegetables, many ornamentals) have had an entirely different history of selection. Cultivars in these crops are not true races but only clonal replications of exceptional individuals, which are as a rule highly heterozygous. They had been picked up by the cultivator from among numerous sexually produced variable individuals and “fixed” by cloning. In terms of selection, the development of a vegetatively propagated cultivar is largely a single-step operation. With the exception of rare somatic mutations, selection is completed the moment the clone is picked up. In traditional fruit tree horticulture, the turnover of clones has been low. Appreciated genotypes were maintained for long periods of time. Thus, clonal crops underwent in cultivation only a few recombination-and-selection cycles. In sharp contrast to sexually reproducing cultivated plants, their cultivars do not represent true breeding races but only clones, which, as a rule, are highly heterozygous and segregate widely when progeny tested. Significantly, the majority of such segregating progeny are not only economically inferior or even worthless, but they often regress toward the means found in wild populations, showing striking resemblance to the wild forms.

The Purpose for which the Plant is Being Grown

In different crops, different parts of the plant body are being used. Some are raised for their vegetative parts (tubers, leaves, stems, etc.). In others the reproductive parts (inflorescences, flowers, fruits, seeds) constitute the used products. Also the choice of the desired plant parts introduces automatically contrasting selection pressures, particularly in regard to the reproductive system of the crops involved.

When crops are *grown for their seeds* (or at least when they are reproduced by seed), they are kept (like their wild relatives) under constant stabilizing selection that keeps their reproductive system intact. Grain crops provide us with the most rigid cases of such normalizing selection. Yields in these crops depend decisively upon the streamlined development of flowers and fruits, normal chromosome pairing in meiosis, and full fertility. Deviants are weeded out automatically and the reproductive system is kept in balance. It is no wonder that among cultivated plants, grain crops are the most conservative

in this regard. They are characterized by strictly balanced chromosome systems and show very little chromosome “problems” under domestication. With very few exceptions (such as the formation of hexaploid bread wheat), the chromosome complements in cultivars of grain crops are identical to those found in their wild progenitors.

Drastic changes in seed fertility (as well as in the chromosome system) can be tolerated when the plants are *grown for their fruits* but are *maintained by vegetative propagation*. Crops in this group (the bulk of the fruit trees) do not depend on seed fertility for their maintenance. Yet they have to keep the basic reproductive growth functions to assure the development of fruits. Moreover, growers usually prefer types in which the size and the number of stones or pips had been reduced, or seedless fleshy fruits. Several solutions for reducing seed fertility without harming fruit set evolve automatically under cultivation. They include the establishment of polyploid clones, some of them meiotically unbalanced (e.g., triploidy in some pears and in bananas), or the incorporation of mutations inducing parthenocarpy—that is, the induction of fruit development without fertilization and without seed set (e.g., bananas, fig, some pears).

Crops *grown for their vegetative parts* and *maintained by vegetative propagation* exhibit the most drastic disruption of their reproductive system and the most variable and bizarre chromosomal situations among cultivated plants. Because such crops are clonally propagated, the conscious selection exerted on them by the growers to increase the output of the desired vegetative part is rarely counterbalanced by normalizing selection to retain sexual reproductive functions. Tropical root and tuber crops provide us with outstanding examples for this development under domestication. Cultivated clones of cassava, yam, sweet potato, or garlic frequently show drastic reduction in flowering. In some, flowering ceases altogether, or almost altogether. When flowers develop they are frequently sterile. Also chromosomally many of these crops are highly polymorphic and frequently contain clones with different levels of polyploidy or variable aneuploid chromosome numbers. Clones may contain 3x, 5x, or even higher meiotically unbalanced chromosome complements. Thus in the yams, *Dioscorea alata* shows all chromosome levels between 3x to 8x; whereas in *D. esculenta*, 4x, 6x, 9x, and 10x forms are known. Sugarcane confronts us with even more complex chromosome pictures. Cultivated clones in this crop are all highly polyploid and frequently aneuploid. Modern cultivars range from $2n = 100$ to $2n = 125$ chromosomes. Older cultivars vary from $2n = 80$ to $2n = 124$.

The Impact of Sowing and Reaping

Traditional grain agriculture is based on *sowing* the seeds of the crop in a tilled field, *reaping* the reproductive parts of the mature plants, and *threshing* out the grains. The introduction of grain plants into such a farming practice initiated, automatically, selection toward the following changes, setting them apart from their wild counterparts.

1. Most conspicuous is the unconscious selection for mutants in which the mature seed is retained on the mother plant

(i.e., for the breakdown of the wild mode of seed dissemination). In cereals this implies a shift from shattering spikes or panicles (in wild forms) to nonshattering ones (in plants under domestication). In pulses it usually means the prevention of the pod from dehiscing and from shedding the seeds. In wild wheat, wild barley, or wild maize, the seed dispersal unit comprises a single internode of the ear. Full disarticulation of the ear, at each segment, is thus an essential element for wild type dispersal, and plants in wild populations are constantly selected for quick shattering of their mature spikes. In contrast, the introduction of planting and harvesting brings about automatic, unconscious selection in exactly the opposite direction. Under the new system a sizable proportion of seed produced by brittle plants will shatter and would not be included in the harvest, whereas all grains produced by nonshattering mutants “wait on the stalks” to be reaped by the grower. Under cultivation, nonshattering individuals have therefore a much better chance to contribute their seed to the subsequent sowing. To summarize, nonbrittle mutants that were totally disadvantaged under wild conditions became highly successful under the new system. Thus, when wild cereals are introduced into the system of sowing and reaping, one should expect selection for nonbrittle forms whether or not the cultivator is aware of this trait. Furthermore, the incorporation of nonbrittle mutants makes the crops fully dependent on humans, as nonshattering plants lose their seed dispersal ability and can no longer survive under wild conditions. For this reason, the presence of nonshattering remains of grain crops in archaeological contexts provide critical indication that these plants were under cultivation. Finally, both theoretical considerations and experimental evidence seem to suggest that at least in wheats and barley, the establishment of nonshattering mutants under the system of sowing and reaping was very likely a fast process. The shift could have been accomplished in the course of several scores of generations.

2. A second major outcome of introducing wild grain plants into this regime of cultivation is the breakdown of the wild mode of their seed germination. Most wild plants, especially annuals, depend for their survival on regulation of their germination in space and time. A common and vital adaptation is a delay of germination and its spread over two or more years. Again, under the system of sowing and reaping such inhibition of germination is automatically selected against. Most grain crops have lost their wild-type germination inhibition patterns. Their seeds germinate fully whenever the farmer plants them.
3. Several other traits characterize cultivated grain crops and are part of the domestication syndrome under sowing and reaping conditions. Because of a rather dense stand in the cultivated field there is a stress to develop forms with erect habit and to reduce the growth of side tillers or branches. Because of the mode of harvest there is a selection for synchronous ripening. In cases of biennial or perennial wild stocks, there is an automatic selection for the shift to annuality. Because the seeds stay protected in the granary, thick shells are selected against. Finally because tilling increases soil fertility there is also a pressure to increase

the number of fertile flowers in the reproductive parts of the crops.

Appendix 1: Crops of Various Regions

This appendix lists the native crops of the various traditional agricultural regions of the world (see *The Traditional Agricultural Systems of the World*). For illustrations and short notes on the various food crops, consult [Vaughan and Geissler \(1997\)](#). The important crops of the world and their evolution are surveyed in [Smartt and Simmonds \(1995\)](#).

Southwest Asia, Mediterranean Basin, and Temperate Europe

Cereals

Emmer and durum-type wheats *Triticum turgidum*
 Einkorn wheat *Triticum monococcum*
 Bread wheat *Triticum aestivum*
 Barley *Hordeum vulgare*
 Rye *Secale cereale*
 Common oat *Avena sativa*

Pulses

Lentil *Lens culinaris*
 Pea *Pisum sativum*
 Chickpea *Cicer arietinum*
 Faba bean (broad bean) *Vicia faba*

Oil or Fiber

Flax *Linum usitatissimum*
 Oil seed turnip *Brassica rapa*

Fruits and Nuts

Olive *Olea europaea*
 Grapevine *Vitis vinifera*
 Fig *Ficus carica*
 Date palm *Phoenix dactylifera*
 Apple *Malus pumila*
 Pear *Pyrus communis*
 European plum *Prunus domestica*
 Sweet cherry *Prunus avium*
 Almond *Amygdalus communis*
 Walnut *Juglans regia*

Vegetables and Spices

Melon *Cucumis melo*
 Watermelon *Citrullus lanatus*
 Onion *Allium cepa*
 Garlic *Allium sativum*
 Leek *Allium porrum*
 Lettuce *Lactuca sativa*
 Beet *Beta vulgaris*
 Turnip *Brassica rapa*
 Cabbage *Brassica oleracea*
 Carrot *Daucus carota*
 Celery *Apium graveolens*
 Parsley *Petroselinum sativum*
 Asparagus *Asparagus officinalis*
 Cumin *Cuminum cyminum*

Coriander *Coriandrum sativum*
 Fenugreek *Trigonella foenum-graecum*

East Asian Agriculture

Cereals and Cereal-Like Grain Crops

Rice *Oryza sativa*
 Foxtail millet *Setaria italica*
 Broomcorn millet *Panicum miliaceum*
 Buckwheat *Fagopyrum esculentum*

Pulses

Soybean *Glycine max*

Oil or Fiber

Hemp *Cannabis sativa*

Vegetables and Spices

Pe Tsai (Peking cabbage) *Brassica pekinensis*
 Pak-choi (Chinese cabbage) *Brassica chinensis*
 Rakkuyu *Allium chinense*
 Chinese chives *Allium tuberosum*
 Ginger *Zingiber officinale*
 Chinese pickling melon varieties *Cucumis melo*

Fruits and Nuts

Chinese chestnut *Castanea henryi*
 Chinese white pear *Pyrus bretschneideri*
 Chinese sand pear *Pyrus pyrifolia*
 Loquat *Eriobotrya japonica*
 Oriental persimmon *Diospyros Kaki*
 Litchi *Litchi chinensis*
 Apricot *Prunus armeniaca*
 Peach *Prunus persica*

Corms and Tubers

Chinese varieties of turnip *Brassica rapa*
 Chinese yam *Dioscorea esculenta*
 Lotus *Nelumbium speciosum*

Stimulants

Tea *Camellia sinensis*

Southeast Asian Agriculture (Including the Indian Subcontinent)

Cereals

Rice *Oryza sativa*
 Job's tears *Coix lachryma-jobi*

Pulses

Sword bean *Canavalia gladiata*
 Mung bean *Vigna radiata*
 Black gram *Vigna mungo*
 Rice bean *Vigna calcarata*

Oil or Fiber

Sesame *Sesamum indicum*
 Tree cotton *Gossypium arboreum*
 Coconut *Cocos nucifera*
 Jute *Corchorus capsularis*

Fruits and Nuts

Banana: cultivated derivatives of *Musa accuminata* and *M. balbisiana*

Citrus fruit crops (several species)

Carambola *Averrhoa carambola*
 Jackfruit *Artocarpus integrifolia*
 Durian *Durio zibethinus*
 Mangosteen *Garcinia mangostana*
 Rambutan *Nephelium lappaceum*

Vegetables and Spices

Cucumber *Cucumis sativus*
 Egg plant *Solanum melongena*
 Black pepper *Piper nigrum*
 Cardamom *Elettaria cardamomum*
 Tumeric *Cucurma longa*
 Nutmeg *Myristica fragrans*
 Cloves *Syzygium aromaticum*
 Ginger *Zingiber officinale*

Corms and Tubers

Taro *Colocasia esculenta*
 Greater yam *Dioscorea alata*
 East Indian arrowroot *Tacca leontopetaloides*

Sugar

Sugar-cane *Saccharum officinarum*

Sub-Saharan African Agriculture

Cereals

Sorghum *Sorghum bicolor*
 Pearl millet *Pennisetum glaucum*
 Finger millet *Eleusine coracana*
 Fonio *Digitaria exilis*
 Teff *Eragrostis tef*
 African rice *Oryza glaberrima*

Pulses

Cowpea *Vigna unguiculata*
 Bambara groundnut *Voandzeia subterranea*

Oil or Fiber

Oil palm *Elaeis guineensis*
 Noog *Guizotia abyssinica*
 Old World cotton *Gossypium herbaceum*

Vegetables and Spices

Gherkin *Cucumis anguria*

Corms and Tubers

Yam *Dioscorea cayenensis*
 Enset *Ensete ventricosa*

Stimulants

Coffee *Coffea arabica*

American Agriculture

Cereals and Pseudo-Cereal Crops

Maize *Zea mays*
 Amaranth *Amaranthus cruentus*
 Amaranth *Amaranthus caudatus*
 Quinoa *Chenopodium quinoa*
 Goosefoot, *Chenopodium berlandieri*
 Marsh elder *Iva annua*

Pulses

Common bean *Phaseolus vulgaris*
Lima bean *Phaseolus lunatus*
Scarlet runner bean *Phaseolus coccineus*
Tepary bean *Phaseolus acutifolius*
Jack bean *Canavalia ensiformis*
Peanut (groundnut) *Arachis hypogaea*

Oil or Fiber

Sunflower *Helianthus annuus*
Island cotton *Gossypium hirsutum*
Upland cotton *Gossypium barbadense*

Fruits and Nuts

Avocado *Persea americana*
Prickly pears *Opuntia ficus-indica*
Sapodilla *Manilkara zapota*
Guava *Psidium guajava*
Passion fruit *Passiflora edulis*
Papaya *Carica papaya*
Pineapple *Ananas comosus*
Chirimoya *Anona cherimola*

Vegetables and Spices

Tomato *Lycopersicon esculentum*
Peppers *Capsicum annuum* and *C. frutescens*
Squashes and pumpkins *Cucurbita pepo*, *C. maxima*,
C. moschata, *C. mixta* and *C. ficifolia*
Vanilla *Vanilla fragrans*

Corms and Tubers

Potato *Solanum tuberosum*
Sweet potato *Ipomoea batatas*
Oca *Oxalis tuberosa*
Ysane *Tropaeolum tuberosum*

Ulluco *Ullucus tuberosus*
Cassava (manioc) *Manihot esculenta*
Cush-cush Yam *Dioscorea trifida*

Stimulants

Cacao *Theobroma cacao*
Tobacco *Nicotiana tabacum*
Coca *Erythroxylon coca*

Glossary

Facilitation Species interactions in which at least one of the participants benefits and neither partner is harmed.

Monoculture Growing a single crop in a field.

Natural enemy A predator, parasite, parasitoid or pathogen of another animal, especially an insect.

Niche complementarity Species that differ in at least one aspect of their resource use, and thereby experience less intense competitive interactions, allowing them to coexist.

Nitrogen Fixation The process by which gaseous nitrogen (N_2) in the atmosphere is converted by biological or chemical means to ammonia and other forms usable by plants and animals.

Polyculture Growing two or more crops in the same field at the same time.

Resilience The rate at which an ecosystem returns to original conditions after a perturbation.

Resistance The degree to which an ecosystem changes in response to a perturbation.

Introduction

The popularity of agriculture as a focus of ecological study has waxed and waned during the past century. Agricultural systems have been touted as model systems for testing ecological theory because of their relatively well-characterized components, simple food webs, and manipulability. In the past, they have often served as effective model systems for plant ecology, plant–insect interactions, and predator–prey theory. In recent years, the growth of sustainable agriculture has resulted in increasing interest in understanding ecological processes in agriculture so that they can be manipulated more effectively for enhancing agricultural productivity and reducing negative environmental impacts of agricultural activities. A variety of types of ecological theory have been applied to agricultural systems, and thus the subdiscipline of “agroecology” encompasses a very broad range of approaches, including physiological ecology, population biology, community ecology, ecosystem ecology, and landscape ecology. All these approaches offer significant insights into the ecology of agricultural systems and provide useful guidelines for improving the functioning of these systems. Because the role of diversity in ecological systems has been a consistent element in much agroecological research, this article focuses on diversity in agricultural systems, with particular attention to areas of agroecology that appear to have the most potential to offer agricultural and environmental enhancement.

Planned and Unplanned Diversity in Agroecosystems

The biodiversity in agroecosystems can be classified as either “planned” or unplanned diversity. Planned diversity includes the spatial and temporal arrangement of domesticated plants and animals that farmers purposely include in the system. It may also include beneficial organisms that are deliberately added to the agroecosystem, such as biological control agents or plant-associated nitrogen-fixing bacteria. Unplanned diversity (or “associated diversity”) includes all the other associated organisms that persist in the system after it has been

converted to agriculture or colonize it from the surrounding landscape. This component of diversity is likely to include a variety of weedy plants, herbivores, predators, parasites, and microorganisms that make up the majority of species in any ecosystem, even a simplified one such as an agroecosystem. It has become increasingly clear that the two components of diversity are significantly linked: As planned diversity increases, the diversity of the associated biota also increases. Although the evidence for the plant-based food web is strongest, this relationship also appears to exist for the detritus-based food web.

Given this relationship between planned and unplanned diversity, how do both types of diversity influence agricultural productivity and other ecological processes that occur in and around agroecosystems? The impact of planned diversity is relatively well understood, but much remains to be elucidated about the role of unplanned diversity in agroecosystem function.

Impact of Planned Diversity on Ecological Processes

Agroecosystems vary dramatically in their complexity and degree of planned diversity, which may include genetic diversity, species diversity, structural diversity, and functional diversity (Figure 1). The input-intensive monoculture systems that dominate commercial agriculture worldwide have low planned diversity and relatively simplified community assemblages. At the other extreme, traditional agricultural systems and home gardens of the tropics often have high planned diversity and complex assemblages of associated biota. This range of planned diversity in existing systems has provided rich opportunities for exploring the impact of planned diversity on a suite of ecological processes, including primary production, pest regulation, decomposition, and nutrient cycling.

Planned Diversity, Productivity, and Stability

The idea that diversity should impart stability to ecological systems, including agricultural systems, dates back at least to

Agroecosystem	Genetic	Species	Structural	Functional
Herbaceous monoculture				
Herbaceous varietal mixture				
Herbaceous polyculture				
Plantation crops				
Agroforestry				
Tropical home gardens				

Figure 1 Degree of different types of planned diversity found in some typical agroecosystems. Intensity of shading indicates degree of diversity. Figure 2 Predicted relationship between productivity and plant species richness. Reproduced from Tscharntke T, Klein AM, Kruess A, Steffan-Dewenter I, and Thies C (2005b) Landscape perspectives on agricultural intensification and biodiversity – ecosystem service management. *Ecology Letters* 8: 857–874, with permission from Wiley.

the 1950s and has stimulated much ecological theory, some empirical research, and extensive debate. Until the 1990s, the best evidence for the idea that diverse systems should be more stable than simple ones came from agricultural ecosystems rather than natural ecosystems. Many agricultural studies have demonstrated increased productivity (i.e., significant yield increases) in diverse cropping systems compared to monocultures. However, the majority of these studies address systems of relatively low plant species richness, comparing monocultures to polycultures of two or three species. We expect that the relationship between productivity and plant species richness should resemble the asymptotic curve in [Figure 2](#), as it appears to do so for natural grasslands ([Tilman et al., 1996](#)) and long-term experimental grasslands ([Tilman et al., 2006](#)), but we have little data to indicate where the asymptote might be. Researchers have speculated that the increase in productivity with increasing species richness in agroecosystems may level out at approximately 10 plant species, although this number is likely to vary according to

crop species identity, type of agricultural system, and environmental conditions.

The tendency of diverse cropping systems to have higher productivity than would be expected on the basis of the productivity of their component crops grown in monoculture is often called “overyielding.” Overyielding may result from niche complementarity or facilitation resulting from a variety of mechanisms, such as more efficient use of resources (light, water, and nutrients) or reduced pest damage. There have been numerous experimental studies examining these mechanisms ([Malezieux et al., 2009](#); [Letourneau et al., 2011](#)). When interspecific competition for a limiting factor is less than intraspecific competition for that factor, overyielding is predicted. Facilitation occurs when one crop modifies the environment in a way that benefits a second crop, for example, by lowering the population of a critical herbivore or releasing nutrients that can be taken up by the second crop. Facilitation may result in overyielding even where direct competition between crops is substantial ([Vandermeer, 1989](#)). Note that not all crop combinations exhibit niche complementarity or facilitation, and not all combinations overyield. For obvious reasons, however, most of the classic polycultures used by farmers over centuries, such as grass–legume mixtures, tend to overyield.

There is evidence that diverse cropping systems exhibit greater yield stability and higher productivity, suggesting that resistance to environmental perturbation may be higher in diverse systems. Yield stability has been measured in at least three ways: by calculating coefficients of variation of yield, by computing regressions of yield against an environmental index, and by estimating the probability of crop failure. Polycultures exhibit greater yield stability according to all criteria. Polycultures tend to have lower coefficients of variation than crops grown as separate monocultures; the response of polycultures to environmental change tends to be as stable or more stable than the most stable component crop grown in monoculture; and polycultures tend to have a much lower probability of crop failure than the component crops grown in monoculture. The probability of crop failure is an estimate of risk and lower probabilities result from both the higher yields of polycultures and the putative yield stability. Overall, studies indicate that diverse cropping systems are

more stable than monocultures, both agronomically and economically.

Several mechanisms may lead to greater yield stability in diverse systems. When one crop performs poorly because of drought or pest epidemic, for example, the other crop(s) can compensate, using the space and resources made available. Such compensation is obviously not possible if the crops are grown separately. If the yield advantages of polycultures are greater under stress conditions, then yield stability is higher. This polyculture advantage has been demonstrated for crops under nutrient stress and drought stress. Moreover, where polycultures lead to reduced pest attack, as they often do (Letourneau *et al.*, 2011), then greater yield stability may result from the dampening of pest outbreaks and disease epidemics.

These processes may operate simultaneously in diverse systems and are consistent with the idea that species richness buffers productivity under conditions of environmental variability and that diversity imparts resistance to perturbation. The ability of polycultures to compensate for losses might also be considered to represent resilience. While systems with greater resistance will be less impacted by a perturbation, systems with greater resilience return rapidly and reliably to original conditions.

Ecological research on the role of diversity in natural grassland systems around the world (Hooper *et al.*, 2005; Tilman *et al.*, 2006) indicates that diverse natural communities may be more productive than simple systems, at least partially as a result of increased nitrogen use efficiency in more diverse systems. These studies also suggest that more diverse plant communities are more resistant to disturbance and more resilient in the face of environmental perturbations such as drought. For example, the productivity of diverse grassland communities appears to decline less during a drought and to return more quickly to predrought levels than is the case for species-poor communities. Research in grasslands thus tends to support the conclusions from agricultural research that diverse plant communities have higher productivity and stability.

Planned Diversity and Pest Regulation

The planned diversity of the agroecosystem has important effects on herbivorous insects and the microbial community attacking crops. Traditional agricultural systems often include substantial planned genetic and species diversity, and genetically diverse grain crops are used in many parts of the world to control pathogens. In contrast, the low planned diversity of most commercial monocultural systems often results in large crop losses from a pest complex that is less diverse but more abundant than that in more diverse systems. The trend for higher pest densities in monocultures compared to diverse cropping systems is especially strong for specialist insect herbivores with a narrow host range. As planned diversity increases, population densities of these specialist herbivores decrease (Andow, 1991). In a recent meta-analysis of experiments on plant diversification in agricultural systems, Letourneau *et al.* (2011) found that herbivores and crop damage were strongly suppressed and natural enemy

populations were enhanced in diversified systems compared to monocultures.

In a classic paper, Root (1973) offered two hypotheses to explain higher densities of herbivorous insects in simple, monocultural systems: the resource concentration hypothesis and the enemies hypothesis. The first hypothesis predicts that herbivores, particularly specialists, in pure, dense host plant stands will be more likely to find their hosts and more likely to survive and reproduce. In contrast, herbivores in less dense or more host plant-diverse stands should be less likely to find their hosts and more likely to lose them. Although the details of herbivore–host interactions vary considerably, subsequent experimental tests of this hypothesis have generally supported it with respect to the effects of diversity (Letourneau *et al.*, 2011), especially for specialist herbivores. Host-finding behavior and insect movement, both colonization and emigration, appear to play important roles in the response of herbivorous insects to agroecosystems. Densities of specialists may be lower in diverse systems because (1) they have difficulty locating hosts due to interference with olfactory or visual cues or (2) they leave hosts more often due to lower plant quality and then have difficulty relocating them. These behaviors are significantly affected by the chemical, nutritional, and structural diversity that accompanies planned plant species diversity.

The enemies' hypothesis predicts that diverse systems should have higher densities of herbivore natural enemies (predators and parasites) because they provide more resources for these natural enemies, such as alternate prey or hosts, nectar, pollen, and refugia. This hypothesis has also largely been supported in experimental studies (Letourneau *et al.*, 2011). Compared to monocultures, diverse systems are likely to have higher predation rates, higher parasitism rates, and higher ratios of natural enemies to herbivores, all of which may contribute to lower pest densities. Natural enemies comprise one component of the unplanned diversity that increases as planned diversity increases in agroecosystems.

Microbial pathogens also respond to the planned diversity of agroecosystems, but their response is more variable than that of herbivorous insects. The majority of plant viruses are transmitted by insects, and these tend to be found at lower incidence in diverse systems due to the effects of plant species diversity on their insect vectors. The impacts of host-specific pathogens are likely to be lower in diverse systems due to density-dependent population growth. However, crop diversification can modify the microclimatic conditions that play an important role in the development and severity of many fungal and bacterial diseases. Pathogen growth and reproduction may be either encouraged or inhibited in more diverse cropping systems, depending on the particular requirements of the organism. The effects of diversity depend on a variety of dispersal processes, infection efficiency, and the rate of disease progress. Interestingly, some experiments in grasslands have shown that low productivity in low-diversity communities can largely be attributed to specialized soil-borne pathogens (Schnitzer *et al.*, 2011).

The genetic diversity of crops can dramatically reduce pathogen impacts on crop productivity. Mixtures of genotypes of a single species, such as multiline cultivars and varietal mixtures, have been used effectively to retard the spread and

evolution of fungal pathogens in small grains and other crops. There is evidence that genetic mixtures may also have lower densities of insect herbivores and a lower incidence of plant viruses. Typically, these mixtures include both resistant and susceptible crop genotypes, although they may be mixtures of several different resistant genotypes. The reduction in pathogen spread is greater than would be expected on the basis of the proportion of resistant genotypes in the mixtures, and therefore it appears to be due to the effects of diversity *per se* on the ability of pathogens to disperse (Mundt, 2002).

High planned diversity that includes genetic diversity, species diversity, and structural diversity thus has a strong influence on populations of herbivorous insects and plant pathogens. The intentional manipulation of planned diversity for the purpose of pest control is common in traditional agricultural systems, and it offers real potential for increasing the productivity of contemporary agricultural systems without the negative environmental impacts of pesticides.

Planned Diversity and Soil Processes

Planned diversity may also have significant impacts on the soil community. Plant pathogens and their antagonists in the soil are well known to respond to crop diversity. Long-term, continuous monoculture can result in dramatic shifts in the competitive balance among microbial species and increase the aggressiveness of plant pathogens. Conversely, populations of plant parasitic fungi, bacteria, and nematodes may decline when monocultures of their host plants are replaced by diverse cropping systems. Rhizosphere microbial communities, including a variety of bacteria and fungi, respond to plant species composition of the cropping system, plant phenology, plant nutrient status, and even plant genotype. Plant mutualists such as mycorrhizal fungi or nitrogen-fixing bacteria may be strongly determined by crop composition and phenology. Some ecological processes such as nitrogen cycling may be substantially controlled by crop diversity and plant composition since the inclusion of legumes can increase rates of biological nitrogen fixation (Drinkwater and Snapp, 2007). Owing to the effects of litter diversity, decomposition rates may also be quite responsive to planned diversity.

Despite increasing awareness of the effects of planned crop diversity on the soil community, our ability to predict the impacts of manipulating planned diversity is limited because our understanding of the complex interactions among soil organisms and between plants and soil microbes is still rather weak. Greater attention to the ecological dynamics of these soil communities under different cropping systems will aid in determining the extent to which we can manage these communities to enhance agricultural productivity using planned diversity.

Unplanned Diversity and Ecological Services

The unplanned diversity that accompanies planned diversity in agricultural systems can provide many ecological services to agriculture. This means that the conservation of biodiversity can offer significant benefits to agriculture. Uncultivated

species, including wild relatives of crops that occur in and around the agroecosystem, are an important source of germplasm for developing new crops and cultivars. Increasing planned crop diversity can augment the resources available to pollinators and to natural enemies such as parasitic wasps, resulting in higher populations of these beneficial organisms. Increasing planned diversity may also foster beneficial soil organisms and the conservation of functional processes, such as decomposition and nutrient cycling.

Overall, unplanned diversity within the agroecosystem affects plant and soil processes that can in turn affect crop productivity. For example, many traditional cacao and coffee systems in the tropics resemble forest ecosystems because they are well shaded and humid, with a diversity of shade trees, a diverse herbaceous understory, and a thick leaf litter layer. These traditional agroecosystems have high planned species diversity, high genetic diversity, and high structural diversity. Studies have shown that shaded cacao and coffee plantations support higher levels of biodiversity than full-sun plantations grown without shade trees, that is, monocultures (Perfecto *et al.*, 1996; Tscharntke *et al.*, 2011). The shaded systems may be traditional “rustic” systems in which the understory of native forests is cleared and the crop is planted under the natural forest overstory. They may also be improved systems in which a few carefully chosen tree species are planted interspersed among the crop. In either case, these shaded systems have high planned diversity accompanied by high unplanned diversity.

Shaded coffee and cacao have been demonstrated to be good habitats for migrant and resident forest birds, as well as bats, and these vertebrates can be important consumers of pest insects. They also contain relatively high diversities of insects, lizards, and other fauna, some of which contribute to pest regulation. Pollination also appears to be enhanced in shaded systems. Since many of the commonly used shade trees are leguminous, the trees reduce the amount of nitrogen inputs required. In addition, the shade provides significant weed control and, at least in cacao, reduces the incidence of several important diseases. The high levels of unplanned diversity thus contribute significantly to agricultural productivity, and recent studies have shown that there is no necessary trade-off between biodiversity and yield (Clough *et al.*, 2011). Moreover, by serving as habitat for a relatively high diversity of vertebrate and invertebrate animals, such agroecosystems may enhance the conservation value of an agricultural landscape.

Unplanned Diversity and Pest Regulation

One of the ecological services provided by the unplanned diversity in agroecosystems is the regulation of herbivorous insects and microbial pathogens by competitors, predators, and parasites. As discussed previously (*see* Planned Diversity and Pest Regulation), high planned diversity often results in higher densities of predators and parasites. Even in agroecosystems of low planned diversity, the diversity of natural enemies may be quite high as long as pesticides are not used. For example, paddy rice monocultures managed without pesticides can have surprisingly high diversities of herbivorous insects, predators, and parasitoids compared to similar

monocultures in which pesticides are used. Recent pest management programs in Southeast Asian paddy rice have taken deliberate advantage of this diversity and drastically reduced pesticide inputs without sacrificing yields. In traditionally managed rice fields, the predators are likely to include fish and amphibians, which contribute to pest regulation and also provide additional nutritional resources for farm families.

Unplanned Diversity and Soil Processes

Despite some significant advances in our understanding of soil processes, we know relatively little about the soil biota and their impact on agricultural productivity. In natural ecosystems, decomposition and soil nutrient cycling are regulated by a diverse community of invertebrates and microorganisms, such as termites, earthworms, nematodes, fungi, and bacteria. The composition, abundance, and activity levels of the soil biota in agricultural systems are markedly different from those in surrounding natural ecosystems. For example, the diversity and abundance of soil insects and earthworms in tropical agroecosystems are typically significantly reduced compared to those of a wide range of undisturbed tropical ecosystems. In cases in which abundance remains high in agricultural systems, the soil communities are often dominated by a single or small number of species highly adapted to the modified environment.

The changes in the soil community under agriculture result from a variety of perturbations to the soil environment. The initial conversion from undisturbed ecosystems typically involves the removal and/or burning of plant biomass followed by tillage – activities which have drastic impacts on soil structure and soil chemistry. The physical changes at the soil surface amplify diurnal and seasonal fluctuations in temperature and moisture. In addition, organic inputs to the soil are significantly reduced as a result of plant biomass removal, and the chemical composition of organic inputs is altered. These extreme modifications of the soil environment can result in the elimination of some soil organisms and, at a minimum, are likely to change the competitive balance among species. To the extent that agricultural systems minimize these perturbations (e.g., by reducing tillage or burning), the impacts on the soil community may be less severe.

Despite these well-known effects of agricultural conversion on the soil community, the link between loss of soil biodiversity and various ecological processes has not been extensively studied. Decomposition and nutrient mineralization, for example, are controlled by the activities of a diverse community of organisms. It is not clear that the loss of some species will result in significant changes to these functions, but the degree of functional redundancy among different species is still controversial. However, some processes such as nitrogen fixation are carried out by very specific organisms, whose loss might substantially affect nitrogen cycling. Given the importance of soil biota for decomposition and nutrient cycling, it is essential that the link between this component of unplanned diversity and ecological processes be explored more fully.

Agriculture and Diversity in the Landscape

Agroecosystems typically sit in a landscape of multiple land uses. Human-modified landscapes fall along a continuum from relatively homogeneous landscapes consisting of a small number of cropping systems to heterogeneous mosaics of diverse cropping systems within a matrix of natural ecosystems. Agricultural activities can have important effects on natural ecosystems through the movement of organisms, pesticides, nutrients, and soil. At the same time, the landscape context can strongly influence ecological processes that occur within agroecosystems, such as pollination and pest regulation. The spatial structure of the landscape, including the size, shape, and connectedness of different ecosystem types can have dramatic effects on these ecological processes.

Consequences of Agricultural Activities

Ecological concepts have often been utilized to address the consequences of agricultural perturbations for natural ecosystems in agricultural landscapes. Agricultural intensification can diminish ecosystem services such as the provision of clean water due to increased nutrients, agrochemicals, and dissolved salts entering groundwater and surface water. Significant sedimentation of waterways and dams results from the loss of riparian vegetation that often accompanies intensification. The impacts of nutrient inputs and pesticides for downstream aquatic and terrestrial ecosystems have been well studied. Much of the pesticide applied to crops fails to reach the target pests and instead moves into adjacent ecosystems, where it can have significant impacts on the diversity and abundance of nontarget species. Studies have shown that pesticides have strong effects on trophic dynamics and a range of ecosystem processes in complex natural ecosystems, both aquatic and terrestrial. Similarly, movement of nitrogen from agroecosystems to natural ecosystems through leaching or deposition may lead to significant impacts at several trophic levels. Increased nitrogen loading may reduce plant species richness while increasing the biomass of dominant species. In response to these changes, both pathogens and herbivorous insects are likely to exhibit lower species richness but higher population abundance, just as they do in agricultural systems. Changes in pathogen and herbivore populations may in turn influence the productivity and fitness of their host plants. Even in the absence of changes in herbivore population pressure, research has shown that the effects of herbivory on plant growth and reproduction may be more severe at high levels of nutrient availability. As with the complex effects of pesticides, these impacts of inadvertent fertilization are likely to impact trophic dynamics and ecosystem processes.

Spillover of Organisms from Agroecosystems

In addition to the movement of soil and agricultural inputs, a variety of organisms move from agroecosystems to natural ecosystems in agricultural landscapes. There is abundant evidence that pathogens move from domestic animals to wild animals (and humans), along with more limited evidence for movement of plant pathogens from crops to wild plants

(Power and Mitchell, 2004). Despite human efforts to breed crops resistant to pests and pathogens, many crops are excellent hosts for a variety of parasites that can spill over to wild hosts. Herbivorous insect pests build up on high quality, nutrient-dense crop hosts and then move to wild host plants, where increased herbivory may have significant effects on plant demography (Tscharntke *et al.*, 2005a). The reproductive success of a number of rare or endangered plant species has been significantly reduced due to herbivores moving from crops (Blitzer *et al.*, 2012). Movement out of crop fields is particularly likely at mowing, harvest, and other times when the crop resource is disturbed, degraded, or diminished. Similar movements have been seen for natural enemies of crop pests, which seek alternative prey in natural habitats when crop pests are no longer available. As a result, enemies that increase in agricultural systems due to high pest densities can suppress the densities of herbivorous insects in natural ecosystems, thereby changing the dynamics of plant–insect interactions.

Finally, there is some evidence for spillover of pollinators from agroecosystems to natural habitats (Blitzer *et al.*, 2012). Many pollinators forage in crop fields, but move to natural habitats to complete their lifecycle. Studies suggest that spillover of bees from agroecosystems may sometimes benefit native plant species in natural habitats by compensating for the decline in native pollinators due to habitat fragmentation and other changes. If pollinators are limiting, however, then crops may compete with native plants for pollination services. In general, organisms that build up in agroecosystems clearly have the potential to modify species interactions and the structure of natural plant communities, but the consequences of movement of organisms from managed to natural ecosystems have not been extensively studied.

Landscape Influences on Ecological Processes in Agriculture

The spatial structure of the landscape can shape many ecological processes in agroecosystems, including water and nutrient uptake by crops, weed dispersal, pest control, and pollination. Globally, the intensification of agriculture has caused a simplification of landscape structure through the expansion of agricultural land, increase in field size, loss of field margin vegetation, and elimination of natural habitat. This simplified landscape structure can affect the movement of organisms across the agricultural landscape, often limiting the movement of wildlife and organisms beneficial to agriculture if natural habitat corridors are not available (Tscharntke *et al.*, 2005b; Kremen *et al.*, 2007). In contrast, wildlife, pests, natural enemies, and pollinators are more likely to move among agricultural and natural habitats in heterogeneous landscapes with smaller, intermixed patches. In some cases, natural habitats provide beneficial organisms with refugia and resources that are unavailable in agroecosystems, thus contributing valuable ecosystem services to agriculture.

Meta-analyses of published studies on the effects of landscape structure on natural enemies and pests in agriculture indicate that landscape complexity often enhances natural enemy populations and biological control of insect pests. Relatively few studies have quantified the direct effects on pest

Figure 3 Predicted relationship between biodiversity and local, farm-level diversification in landscapes of varying diversity. Reproduced from Tscharntke T, Klein AM, Krüess A, Steffan-Dewenter I, and Thies C (2005b) Landscape perspectives on agricultural intensification and biodiversity – ecosystem service management. *Ecology Letters* 8: 857–874.

populations, but there is some evidence that landscape simplification leads to higher population growth rates of pests and greater plant damage (Chaplin-Kramer *et al.*, 2011). One unresolved issue is whether pests and natural enemies respond to landscape complexity at different spatial scales. Some studies have suggested that enemies may respond at smaller scales than pests, and that parasitoids respond at smaller scales than other enemies. Meta-analyses do not strongly support the overall difference between pests and enemies, but they indicate that specialist natural enemies such as parasitoids may respond to landscape structure at smaller spatial scales than generalist natural enemies such as predators (Chaplin-Kramer *et al.*, 2011). As a rule, natural enemies that are capable of dispersing long distances are more likely than weak dispersers to survive in simplified agricultural landscapes with few or distant patches of natural habitat. As described above, crop diversification and management of seminatural habitat, such as hedgerows or field borders, within a single farm can also lead to higher natural enemy populations. However, farm-level diversification is more likely to influence pests and natural enemies if the wider landscape is structurally simple, than if it is already heterogeneous with many patches of natural habitat (Figure 3). Within complex landscapes, pest control services may not be significantly affected by additional farm-level diversity (Tscharntke *et al.*, 2005b; O'Rourke *et al.*, 2011). Landscapes that completely lack natural habitat, however, may have such a limited species pool of natural enemies that farm-level diversification may not result in notable increases in pest control services.

Like natural enemies, pollinators tend to be more abundant in complex landscapes with patches of natural habitat. Pollination by bees or other animals significantly improves productivity for more than 70% of globally important crops. As honeybee populations have declined due to disease, pollination by wild bees has become an essential ecosystem service provided by natural habitats. Agricultural intensification threatens wild bee communities and may destabilize

pollination processes at the landscape level. Both pollinator visitation to crops and the species richness of pollinators decline with increasing distance from natural habitats, and the decline is steeper in tropical landscapes compared to temperate landscapes (Ricketts *et al.*, 2008). This implies that a heterogeneous landscape with intermixed patches of agriculture and natural vegetation would be most successful in delivering pollination services to agriculture.

Future Directions

Although the study of agricultural ecosystems has provided many insights into the role of diversity in agroecosystem function and the ecological impacts of agriculture, the sub-discipline of “agroecology” is still in its infancy. Two areas that urgently warrant more attention from ecologists are (1) the influence of planned and unplanned agroecosystem diversity on soil processes such as decomposition and nutrient cycling and (2) the functional consequences of landscape complexity for community structure in agroecosystems and natural habitats. A better understanding of the ecological processes operating in both areas could result in significant benefits to both agriculture and environmental protection.

Glossary

Ecosystem services Benefits that nature provides people, such as food, water purification, climate regulation, pollination, waste decomposition, and spiritual values.

Invasive species Plant or animal species that disrupt an ecosystem's composition, structure, function, or the processes that maintain it.

Regime shift A large, persistent, often abrupt change in the structure and function of an ecosystem associated with a change in dominant feedback processes.

Scenarios Alternative outcomes developed to identify and manage uncertainty in complex problems.

Tipping point A threshold separating two alternate regimes or configurations in the structure and function of an ecosystem (also see regime shift).

Agriculture is the biggest driver of land-use change on the planet. The strain of agriculture on biodiversity is only increasing as demand for food and other agricultural goods continue to increase. How will we manage to feed a future world and protect biodiversity? How much can changes in management practices alone meet future food demands while decreasing the environmental costs? What new developments are needed? And what are the mechanisms for protecting biodiversity on a planet that is increasingly managed more intensively to sustain and improve human livelihoods? This article summarizes the scope of agriculture, its effect on biodiversity, and strategies for feeding the world while maintaining biodiversity.

The Scope of Global Agriculture

Nearly 40% of the ice-free land on earth has been converted to pastures or croplands to feed people (Foley *et al.*, 2005; Ramankutty *et al.*, 2008; Figure 1). Pastures and croplands cover ~28 million km² and ~15 million km², respectively (Ramankutty *et al.*, 2008). To put these numbers in perspective, the areas of pasture and croplands are nearly equivalent to Africa and South America, respectively. Croplands cover 20% of temperate regions, compared with ~10% of tropical regions (West *et al.*, 2010). Wheat, rice, and maize are the most dominant crops, covering over a third of the total crop area.

Several projections estimate that agricultural production will likely need to double (or more) by 2050 to meet the growing demands for agricultural production. According to the United Nation's Food and Agriculture Organization, agricultural lands were expanding at a rate of ~10 million ha each year between 1980 and 2007. This expansion is driven by three main factors. First, food demand is increasing to feed a growing population. Second, more people are eating meat as a substantial part of their diet as wealth and preferences change. Depending on the animal species, it takes 2–30 cal of feed to produce a calorie of meat, reducing the efficiency of the number of calories “delivered” from each area of cropland. Finally, many countries are increasing crop production for biofuels as a means of reducing greenhouse gas emissions. Recent concerns over the trade-off of food security and energy make the rate of increase in biofuel production uncertain.

In addition to the land footprint, a tremendous amount of water is used to produce food. During the past 50 years, the area of irrigated croplands has doubled and accounts for 70% of total water withdrawals (Gleick, 2003). Much of this water is “consumed,” meaning that it either evaporates from the ground or is transpired by plants, and is not immediately available in rivers, lakes, or groundwater. Irrigation is most intense in arid regions, which most commonly have stressed water supplies for people and biodiversity as well as crops.

Fertilizer use has also increased dramatically in the past 50 years. The development and commercialization of producing synthetic nitrogen gave farmers easier access to fertilizers to increase crop yields. As a result, yields have doubled in

Figure 1 Distribution of croplands and pastures. In 2000, ~15 million ha were used for croplands and ~28 million ha were used for pastures. Data from Ramankutty N, Evan AT, Monfreda C, and Foley JA (2008) Farming the planet: 1. Geographic distribution of global agricultural lands in the year 2000. *Global Biogeochemical Cycles* 22: GB1003. doi:10.1029/2007GB002952.

many places. Unfortunately, these nutrient additions have not only increased crop yields, but they have also increased the amount of excess nutrients in the environment. The annual flows of nitrogen and phosphorus have doubled their natural levels as a result of fertilizer inputs (Matson *et al.*, 1997; Smil, 2000).

Effects of Agriculture on Biodiversity

Species loss is occurring 100 times faster than the average rate in the fossil record (Dirzo and Raven, 2003). Much of this extinction is attributed to habitat loss from conversion to croplands and pastures. Although it is critical to consider extinction because it is irreversible, land conversion for agriculture has a much broader effect on ecosystem degradation through habitat loss and fragmentation. Populations and ecosystems (as well as other levels of biodiversity) are also altered through indirect effects on climate, water quantity, water quality, and invasive species.

Habitat Loss

Clearly the most direct effect of agriculture on biodiversity is converting natural ecosystems for agriculture. While there are some exceptions, such as planting coffee trees within a selectively cleared forest or grazing on natural grasslands, the species composition of agricultural lands rarely resembles the natural ecosystem that it replaced. However, some agricultural systems, such as pastures and forage crops, provide surrogate habitat for species groups in decline, such as grassland birds.

The distribution of croplands and pastures is a function of climate, technology, crop selection, and cultural traditions. Grasslands have experienced the most conversion, primarily because they exist in climates suitable for many crops, are easily used as pastures, can be converted to croplands much easier than forests, and generally have productive soils. Other ecosystems have also had substantial conversion to croplands and pastures (Table 1).

Although extensive areas of many natural ecosystems remain, their habitat quality has been degraded. Agricultural areas have fragmented ecosystems into smaller blocks, which favor species that are tolerant of (or thrive in) disturbed environments at the expense of species restricted to higher quality areas. These simplified ecosystems are less resilient to large disturbance events because fewer components of the former system are able to rebuild, or reorganize, following a major shock.

Climate Change

Clearing land for agriculture has indirect effects on biodiversity through climate change. Deforestation accounts for 12% of global CO₂ emissions (van der Werf *et al.*, 2009). The climate effects of clearing land are particularly strong in the tropics. Nearly all CO₂ emissions from deforestation (98%) originate in tropical regions (DeFries and Rosenzweig, 2010), where agricultural lands are expanding fastest. In addition to the high rate of expansion, tropical ecosystems typically store more than twice as much carbon per hectare as temperate ecosystems (West *et al.*, 2010; Figure 2). Unfortunately, these high carbon losses are coupled with loss of habitat in tropical areas that typically have high species diversity and endemism.

Table 1 Percentage of biomes converted for agriculture

Biome	Potential biome area (millions of ha)	Percent converted to pasture (%)	Percent converted to cropland (%)
Tropical evergreen broadleaf forest/woodland	1675.1	10.8	8.5
Tropical deciduous broadleaf forest/woodland	584.0	27.0	23.8
Temperate evergreen forest/woodland	113.1	24.2	18.6
Coniferous forest	361.0	20.0	9.8
Temperate deciduous forest/woodland	482.9	30.0	16.2
Mixed forest	597.6	1.5	1.7
Boreal evergreen forest/woodland	221.0	1.7	1.8
Boreal broadleaf forest/woodland	1494.4	7.7	4.5
Savanna	1912.2	15.7	32.5
Grassland/steppe	1424.9	19.2	49.2
Dense shrubland	597.5	17.9	29.5
Open shrubland	1190.6	7.3	42.3
Tundra	703.9	0.6	12.9
Desert	1530.0	0.9	7.9
Polar desert	124.3	0.1	1.7

Source: Using data on croplands and pasture distribution (Ramankutty *et al.*, 2008) and natural biomes (Ramankutty and Foley, 1999), we calculated the percentage of each natural biome converted to pasture and cropland.

Figure 2 Carbon loss from clearing natural ecosystems. Clearing land for agriculture releases carbon stored in natural vegetation as carbon dioxide, a greenhouse gas. The map above illustrates carbon loss for areas currently utilized for croplands. On average, clearing land in the tropics releases twice as much carbon as in temperate regions (~ 120 vs. ~ 64 ton ha^{-1}). Tropical rainforests commonly store $175\text{--}200$ ton ha^{-1} of carbon. Data from West PC, Gibbs, HK, Monfreda C, *et al.* (2010) Trading carbon for food: Global comparison of carbon stocks vs. crop yields on agricultural land. *Proceedings of the National Academy of Sciences of the United States of America* 107: 19645–19648.

Agriculture is also a major contributor of other greenhouse gases, methane and nitrous oxide emissions, accounting for 50% and 60%, respectively, of annual global emissions (Smith *et al.*, 2007). The primary sources of these emissions are from rice production, livestock indigestion, and excess fertilizers.

Combined, agriculture accounts for 30–35% of total annual greenhouse gas emissions (Smith *et al.*, 2007; van der Werf *et al.*, 2009; DeFries and Rosenzweig, 2010).

In addition to greenhouse gas emissions, clearing natural ecosystems can alter regional climate through changes in how

the Sun's incoming energy is absorbed and released by the land surface. When forests are cleared for croplands and pastures, more sunlight is reflected from the land back to the atmosphere. In the tropics, this creates a warming effect because such a large portion of the absorbed sunlight is released by the land in the form of sensible heat, which warms the air. In the boreal forest region, land clearing results in a cooling effect because several months of snow cover reflects so much more energy than the dark forests that were cleared. The effects of land clearing are less dramatic in many other biomes, but the magnitude of effects on regional climate in tropical and boreal regions is as strong as predicted climate responses to greenhouse gas emissions (West *et al.*, 2011).

Water Quantity

In addition to its effects on climate, agriculture has a large effect on water availability. To provide the right amount of water for crops, many farmlands have managed to increase or decrease the water quantity on the fields. As previously mentioned (*see* The Global Scope of Agriculture), more water is consumed for agriculture than any other use on the planet. Withdrawals in some regions are so extreme that major rivers such as the Colorado and the Yellow no longer reach the ocean every year. In another extreme example, in 2007 the Aral Sea was only 10% of its size when irrigation projects began in the Soviet Union in the 1960s. All three of these examples occur in regions with intensive surface water diversions. Other regions are using groundwater for irrigation much faster than it is being replenished, leading to longer term water shortages.

In other regions, croplands are managed to reduce water on the fields. Management practices such as levees are designed to keep rivers from their floodplains in order for them to be farmed. Wet soils are drained through tile drainage and ditching practices. In tropical regions, replacing forests with crops generally increases stream flows and potential flooding because the deep-rooted evergreen trees that transpire water throughout the year are replaced with season annual plants. For example, average daily stream flow substantially increased after replacing tropical savannas forest and savanna with soybeans in the southern Amazon (Costa *et al.*, 2003; Hayhoe *et al.*, 2011).

These water management practices not only improve crop yields, but also alter river flows. Many ecological processes and species have adapted to the natural flow regime, or flood pulse. The quantity, timing, and duration of flow events are all important for biodiversity. Too much or too little disrupts the ecosystem. Changing the flow regime alters nutrient cycling as well as many aquatic species that have aspects of their life cycle that coincide with the natural ebb and flow of water (Junk *et al.*, 1989; Richter *et al.*, 1997).

Water Quality

High fertilizer application rates are common in many places with crop or fertilizer subsidies. Such practices result in excess nutrients, leading to degraded water quality. Excess phosphorous in freshwater lakes and rivers promotes eutrophication. Since phosphorous is a limited nutrient in freshwater

ecosystems, additional input stimulates algal growth, which reduces oxygen and sunlight for other species higher in the food web. Although it is not a limiting nutrient in freshwater systems, nitrogen has similar oxygen-depleting effects in coastal areas. Since the 1960s, the number of hypoxic or "dead zones" resulting from nutrient-rich rivers has doubled from 200 to more than 400 today (Diaz and Rosenberg, 2008).

Other major sources of water quality degradation from agricultural lands include sediment loss and pesticides. Soil tillage and intensive grazing cause soil loss from fields and pastures. If not deposited elsewhere in the field or pasture, eroded soil loss accumulates in aquatic ecosystems. Excessive sediment loads increase turbidity of the water, limiting light penetration and thus plant growth. In addition, nutrients and pesticides are commonly attached to sediment particles. These water quality effects primarily degraded aquatic ecosystems by promoting disturbance-tolerant species at the expense of conservative species, thus simplifying the ecosystem and making it more susceptible to further disturbance.

Invasive Species

Several species introduced to improve agricultural production have had negative effects on natural ecosystems. For example, fast growing, foreign grasses introduced to improve forage production commonly invade natural grasslands. In other cases, plants introduced to control erosion from steep slopes also establish in native ecosystems and replace native species. If we take a broader perspective on agriculture, trees introduced for agroforestry, timber products transported across regions, and fish introduced for aquaculture are all major vectors for invasive species introductions.

Thresholds of Biodiversity Loss

Degradation in response to ecosystem stresses is not always gradual. Regime shifts are large, abrupt, persistent changes in the structure and function of a system (Scheffer *et al.*, 2001). Such shifts occur when a tipping point or threshold is reached, triggering a switch in the dominant feedback processes structuring a system. Regime shifts have been studied in mathematical models and empirically documented in a variety of terrestrial and aquatic systems, including coral reefs, aquatic food webs, savannas, and the climate system (Table 2). Tipping points are a major concern for scientists, managers, and policymakers because of their potentially large impacts on biodiversity, ecosystem services, and human well-being, and because they tend to be difficult to predict, hard to control once they begin, and slow and expensive to reverse once they have occurred.

Human demands for food, fiber, and energy play a key role in driving many regime shifts especially through the conversion of natural and seminatural ecosystems to farming and the overexploitation of marine resources. While global biodiversity assessments have emphasized the significance of these drivers, the potential importance of thresholds, amplifying feedback and time-lag effects leading to regime shifts have received less attention. Most regime shifts result from complex feedback mechanisms or interactions between two or more drivers that

Table 2 Documented regime shifts and associated key drivers and ecosystem service impacts

<i>Regime shift</i>	<i>Key drivers</i>	<i>Ecosystem service impacts</i>
Freshwater eutrophication	Fertilizer runoff	Freshwater, fisheries, water purification, pest and disease regulation, recreation, and aesthetics
Coral–algae shifts	Fishing, disease	Fisheries, natural hazard protection, tourism, and aesthetics
Coral bleaching	Sea surface temperature	Biodiversity, fisheries, natural hazard protection, tourism, and aesthetics
Soil salinization	Clearing of deep-rooted vegetation	Food crops, water purification, and regulation of soil erosion
Bush encroachment	Overgrazing, fire suppression, and exclusion of browsers	Livestock production, woodfuel, and climate regulation
Forest – savanna biome shifts	Deforestation and forest degradation	Biodiversity, freshwater, food crops, livestock, timber, woodfuel, climate, and water regulation
Arctic summer sea ice	Greenhouse gas emissions	Wild animal and plant foods, climate regulation, and water regulation
Thermohaline circulation	Freshwater influx due to climate warming	Fisheries, food crops, livestock, and climate regulation

are not well accounted for in global change models. Because of this, the risk of substantial biodiversity losses, such as widespread Amazon forest dieback resulting from interactions between deforestation and climate change, have been substantially underestimated in earlier global change projections (Leadley *et al.*, 2010). Similarly, recent tipping point analyses indicate that rising atmospheric CO₂ concentrations and climate change could lead to important regime shifts at levels near or below the 2 °C global warming defined by the International Panel on Climate Change (IPCC) as “dangerous,” including widespread coral reef bleaching, large shifts in marine plankton community structure, and extensive invasion of tundra by boreal forest (Leadley *et al.*, 2010).

Regime shifts are associated with species extinctions, declining species abundance, or shifts in species and biome distributions, as well as large impacts on ecosystem services and human well-being. For example, widespread degradation and loss of natural coastal habitats due to pollution, habitat destruction, changes in sedimentation, and sea-level rise are accompanied by increased risk of coastal damage by waves and storm surges as well as the loss of productivity of coastal fisheries. Biodiversity loss and the erosion of the capacity of ecosystems to deliver services often respond in similar ways to shared drivers; however, the relationship between them is not simple and may be different for the various dimensions of biodiversity. For example, the links between local species extinctions and reduced capacity to deliver ecosystem services remain, in many cases, elusive.

Experiments, observations, and models indicate that changes in ecosystem services are more tightly coupled to changes in the abundance and distribution of dominant or keystone species than to species extinctions. This calls for increased awareness of the importance of shifts in species distribution and changes in local abundance as the principal drivers of change in ecosystem services. While it is certain that regime shifts will occur in the future, the dynamics in most cases cannot yet be predicted with enough precision and advance warning to allow for secure and adequate approaches to avoid or mitigate impacts. This reality argues for a precautionary approach to human activities that are known to drive biodiversity loss, since

lags in the socio-economic, biological, and physical systems of the Earth mean that many regime shifts are essentially irreversible over decadal to centurial time scales.

Creating a Sustainable Future

Most future planning efforts are based solely on our current and past needs and constraints. Yet these too are dynamic. In general, increases in food production will need to come from existing agricultural lands if we are to both feed a growing population and protect biodiversity. Below we summarize a set of future scenarios that addressed the trade-offs of agricultural production and biodiversity, the agricultural practices that have the greatest effect on biodiversity, and mechanisms for affecting change through policy and market-based incentives.

Alternative Scenarios

Over the past decade a number of large, integrated scenarios have been developed to explore alternative future development trajectories of the world and their implications for the environment. These include the scenarios developed by the Millennium Ecosystem Assessment (MA, 2005), the Global Biodiversity Outlook 2, the Global Environmental Outlook 4 (UNEP, 2007), the IPCC Special Report on Emission Scenarios (IPCC, 2000), and the International Assessment for Agricultural Science, Technology and Development (McIntyre *et al.*, 2009). These exercises typically start with the development of a limited number (3–5) of “storylines,” which are then quantified using a variety of models to explore their consequences for agricultural development, biodiversity loss, etc. A summary of the Millennium Assessment scenarios and their impacts are given in Table 3.

Synthesizing the results from these studies indicates that land-use change, modification of river flow, freshwater pollution, and exploitation of marine resources are currently the most important drivers of biodiversity change and are projected to remain so over the coming century. Climate change and ocean acidification will also become increasingly

Table 3 Millennium Ecosystem Assessment scenarios

	Storyline summary	Agricultural land in 2050 (million km ²) ^a	Loss of vascular plant diversity 1970–2050 (%) ^b
Global orchestration	Global economic liberalization with strong policies to reduce poverty and inequality, substantial investment in public goods, for example, education	55	13
Order from strength	Economies become more regionalized, nations emphasize their individual security	60	16
Adapting mosaic	Regionalized economies, but with an emphasis on multiscale, cross-sectoral efforts to sustain ecosystem services	54	12
TechnoGarden	Globalized economy with substantial investments in sound environmental technology, engineered ecosystems, and market-based solutions to environmental problems	54	12

^aPasture and cropland. Extent of agricultural land in 1970=46 million km² and in 2000=51 million km².

^bRelative loss when populations reach equilibrium at reduced habitat levels.

The table above summarizes possible agricultural land extent and vascular plant diversity in 2050 under four scenarios. Note that moderate biodiversity losses at the global level can translate to dramatic losses at the regional level or for particular species groups.

important (Leadley *et al.*, 2010). Projections of the impacts of these drivers on biodiversity show continuing and, in many cases, accelerating species extinctions and loss of natural habitat, as well as significant changes in the distribution and abundance of species and biomes over the twenty-first century. The greatest impacts involve large, highly visible modifications of ecosystems, including widespread conversion of tropical forest to pastures and croplands, climate-induced invasion of tundra by boreal forest, and reductions in the abundance of top predators in marine systems (Pereira *et al.*, 2010).

However, all is not doom and gloom. Analysis across different scenario studies highlights that there exist plausible development pathways with low greenhouse gas emissions and low land conversion rates, which could lead to much lower biodiversity impacts. These optimistic scenarios require fundamental changes in development paradigms, but are consistent with known constraints on economics, resource use, and human development goals (Pereira *et al.*, 2010).

However, if greenhouse gas emissions continue along current trajectories, several new models indicate that this will result in far greater climate-induced transformations of terrestrial biomes and marine biota than previously estimated. Furthermore, lags in the underlying socio-economic, climate, and biogeochemical drivers make increased biodiversity impacts inevitable over the next several decades. These lags mean that mitigation and adaptation measures aimed at reducing biodiversity impacts must be taken well before large impacts on biodiversity are observed.

Focusing Agriculture-Related Conservation Strategies

Strategies that aim to both increase food production and protect biodiversity need to focus on reducing the main negative effects of agriculture on biodiversity summarized above (see Effects of Agriculture on Biodiversity). Foley *et al.* (2011) advocate four strategies that would greatly increase food production while improving the environment. First, stopping agricultural expansion will reduce the rate of

biodiversity loss as well as reduce greenhouse gas emissions. Second, improving yields on existing croplands increases food production and reduces the need for expansion. Third, water availability and quality can be improved by increasing the resource efficiency of agricultural production. Many gains in efficiency can be made through existing practices, such as changing fertilization rates and timing, irrigation methods, and livestock feed (reducing methane gas). Genetic improvements are a longer term solution that may generate more nutrient and water-efficient crop varieties. Finally, shifting our diets to be more plant based would reduce the need for agricultural expansion because a greater portion of the crops grown would be directly consumed by people, bypassing the inefficiencies of growing feed to produce livestock.

Meeting Agriculture and Conservation Goals: Mechanisms for Change

Implementing these four strategies will require a mix of policy and market-based incentives at multiple levels. The agricultural and conservation communities have made substantial progress increasing crop yields and protected areas, respectively. Regarding crop yields, agricultural investments in regions with low yields and inefficient use of water, fertilizers, and pesticides offer major opportunities for simultaneously enhancing food production. Underinvestment in agriculture, particularly in Africa, Latin America, and Eastern Europe, have led to significant yield gaps when compared with similar growing regions elsewhere around the world (Licker *et al.*, 2010; Neumann *et al.*, 2010). By one estimate, worldwide crop production could be increased by 60% if the yield gaps were closed for 17 major crops, thereby alleviating the demand to put new areas into cultivation (Johnston *et al.*, 2009). Investments in increased production must also enhance resource efficiency and farm management, including improvements in irrigation management, water harvesting and conservation, and integrated pest management (IAASTD, 2009; ten Brink *et al.*, 2010).

Historically, conservation policy has focused on increasing protected areas by keeping people apart from nature – limiting hunting, farming, grazing, and other human activities in protected areas. Today, over 105,000 protected areas cover about 21 million km², or 11%, of the world's land surface (West *et al.*, 2006). There is no doubt that this system of modern protected areas, begun in the nineteenth century with the national park systems of USA and great game reserves of colonial Africa, has been a critical tool for conservation. Many conservation groups and international policy focus their efforts, by targeting biodiversity protection in globally important regions (e.g., Olson and Dinerstein, 1998; Myers *et al.*, 2000).

Strategies to shift dominant patterns of production and consumption, however, are also needed in a world where the growth of population, resource use, and international trade create powerful incentives to convert sensitive habitat into agriculture and intensify production on existing farmlands. Monitoring and enforcement costs, as well as ethical objections to the criminalization of traditional livelihoods, make the search for alternative models all the more pressing (Karieva and Marvier, 2007). While protected areas that regulate land use directly will continue to play a role in conservation, indirect strategies will create new options for how people use the land.

Strategies focused solely on agricultural goals or solely focused on conservation goals will continue, but the fact is that food production and biodiversity conservation are mutual goals across a large part of the planet. Increasingly, strategies are needed that support agricultural production and biodiversity conservation, promoting smarter approaches to achieving these twin goals and managing necessary trade-offs more effectively. The following paragraphs provide examples of a number of potential mechanisms for change within agricultural policy and market-based approaches.

Agricultural Policies

Policies aimed at decreasing the environmental effects of agriculture have been in place for decades. In the USA, for example, the 1985 Conservation Reserve Program furthered policies begun in the 1950s to make direct payments to farmers to keep their land out of production. More recently, a number of states, provinces, and countries have adopted new policies that aim to maintain some semblance of the natural flows of rivers as part of a comprehensive water management strategy. These efforts improve upon earlier policies designed to maintain a minimum flow in rivers, with the intent of managing the river flows within the ecological limits of hydrologic alteration (Poff *et al.*, 2010).

Opportunities also exist for maintaining and enhancing on-farm agrobiodiversity. Some farmlands house a surprising range of nonfarm species, while maintaining high levels of domesticated plant and animal diversity (Daily *et al.*, 2001). Yet, agrobiodiversity is in decline. Single-minded policies intent on increasing production have favored biodiversity-poor monocultures growing genetically homogeneous cultivars. Increasing support for agrobiodiversity could resist this trend through both *ex situ* conservation in seed banks through organizations like the Consultative Group on International Agricultural Research (CGIAR) and the Svalbard Global Seed

Vault (Global Crop Diversity Trust, 2007), as well as the *in situ* conservation of traditional cultivars and farming systems like the Potato Park in Peru (Argumedo, 2008).

Policies to shift agricultural economic incentives offer promising means to steer land use in a way that better navigates the trade-offs between agriculture and biodiversity. Currently, decisions made on what, where, and how to farm are primarily influenced by economic signals on the agricultural commodities that can be sold in markets. Immediate benefits to biodiversity could be gained by eliminating public subsidies that make the market price for crops artificially high. Entrenched economic and political interests, however, mean this tactic is difficult, time-consuming and, at times, at odds with the goals of social welfare and rural development.

Market-Based Approaches

As biodiversity and ecosystem services become more measurable and transparent, there will be increasing opportunities to incorporate these values in market-based approaches – internalizing costs that historically have been considered free and external to market systems. Several market-based mechanisms could facilitate this change for the agriculture sector, including payment for ecosystem services (PES) approaches, sustainability measures and certification schemes, and mitigation programs employing biodiversity offsets.

PES mechanisms can improve land-use and resource management in a manner that benefits service users and providers and supports conservation goals. While PES programs can differ substantially, the general approach involves service users compensating service providers for practices that support provision of a defined service (Wunder *et al.*, 2008). For example, many PES projects have been established to support improved watershed management. Downstream users of water (i.e., cities and industrial users) benefit from upstream land-use management, often implemented by agricultural communities. Such management practices may include erosion and sedimentation control, forest protection and management, and other steps to ensure water quality and supply. This approach can benefit both parties and nature conservation, as downstream users secure service improvements and upstream providers are compensated for the opportunity costs of changes to their management practices (e.g., preventing grazing on steep slopes).

The most significant PES policy related to agriculture and biodiversity currently being negotiated is a proposal for reducing emissions from deforestation and forest degradation (REDD). Initially conceived as a tool to reduce carbon emissions from tropical rainforests by transferring payments for forest conservation from developed to developing countries, the concept has evolved to recognize biodiversity, poverty reduction, and other benefits a global forest conservation policy could potentially provide. To work, REDD will need to devise a system to ensure accountability, compliance, and payment mechanisms that will change incentives for deforestation on the ground.

Certification programs and sustainability metrics are likely to play a stronger role in the agricultural sector as consumer demand increases for information about food production, businesses increase their focus on accountability within their supply chains, and measures improve for biodiversity and

ecosystem services impacts and uses. Certification schemes evaluate environmental and social performance to distinguish sustainable production practices from “conventional” agriculture, on the premise that consumers will prefer to buy or pay more for certified goods and services – organic, shade-grown, etc. (Bishop *et al.*, 2009). However, there are significant challenges to certification mechanisms, including costs of becoming certified (which can especially disadvantage small-scale producers), risks of changing farming practices, and confusion about the proliferation of sustainability metrics and programs (e.g., ISO standards, Global Reporting Initiative, Roundtables on sustainable biofuels, palm oil, soy, and other commodities). Nonetheless, with consumers increasingly wanting to support responsible brands, and companies seeking to enhance their brands and customer relations, the role of certification is likely to grow as an important means for conveying a brand’s environmental and social performance.

Mitigation programs increasingly employ biodiversity offsets to address the footprint impacts of large-scale projects, such as those from mining, energy, infrastructure, and commercial agriculture projects. The aim is to support smarter development and mitigation decision making in order to maintain the conservation values and ecosystem services upon which people and nature depend. Biodiversity offsets compensate for residual environmental impacts of planned developments after appropriate steps have been taken to avoid, minimize, and/or restore impacts on site. Offsets are emerging as widely employed mechanisms advanced within the mitigation policies of a wide range of countries (McKenney and Kiesecker, 2010), in the sustainability policies of a number of major companies, and through science-based frameworks such as the Nature Conservancy’s *Development by Design* (Kiesecker *et al.*, 2010). Although these mitigation programs are more commonly applied for energy, mining, and infrastructure projects, they have great potential to support sustainability goals for commercial agriculture, especially where it is expanding at the forest frontier (e.g., Brazil and Indonesia).

As illustrated above, there are many promising approaches for managing the trade-offs of agricultural production and biodiversity conservation. These interventions need to be targeted at specific threats in particular places in order to achieve the greatest benefit. Although biodiversity conservation or agricultural production may be the primary goal in some places, the challenge remains to manage the synergies and trade-offs between conservation and agricultural goals across the majority of the landscape. Finding the right mix of policies and incentives will depend on many factors, including food security, economics, and cultural practices.

Conclusion

Protecting biodiversity while increasing food production will require strategies that focus on the main drivers of biodiversity loss and degradation by agriculture on biodiversity: habitat loss and degradation, climate change, water quantity and quality, and invasive species. Particular emphasis should be placed in the tropics, where crop yields are lowest, the food security need is high, agricultural lands are expanding at the fastest rate, and the effects on species loss and climate change

are highest. Most of the existing policies and market-based strategies are targeting decreasing habitat loss and the associated greenhouse gas emissions. New and improved strategies are needed to manage lands and waters to increase food production while decreasing the environmental impacts.

Glossary

Herbicide Chemical used to suppress or kill plants, or to severely interrupt their normal growth processes.

Herbicide resistance Inherited ability of a plant to survive and reproduce following exposure to a dose of herbicide normally lethal to the wild type. In a plant, resistance may be naturally occurring or induced by techniques such as genetic engineering or selection of variants produced by tissue culture or mutagenesis.

Herbicide tolerance Inherent ability of a species to survive and reproduce after herbicide treatment.

This implies that there was no selection or genetic manipulation to make the plant tolerant; it is naturally tolerant.

Integrated weed management Approach for suppressing weeds that combines information on the biology and

ecology of the weed with all available control technologies so that no one method is used exclusively.

Postemergence herbicide Herbicide applied after the emergence of the specified weed or crop.

Pre-emergence herbicide Herbicide applied to the soil prior to the emergence of the specified weed or crop.

Selectivity Phenomenon in which some plants are killed with doses of herbicides that have little or no effect on other plants.

Weed Plant that interferes with the growth of desirable plants and is unusually persistent and pernicious. Weeds negatively affect human activities and as a result are undesirable.

Weed control Reducing or suppressing weeds in a defined area to an economically acceptable level without necessarily eliminating them.

Herbicides are used in agricultural, aquatic, forest, and wildland ecosystems to reduce the density of unwanted vegetation (weeds) and to permit the growth of desirable species. Over time, use of herbicides in agroecosystems reduces weed density and may also select species that are adapted to the particular chemicals, thereby reducing weed species diversity. In wildland ecosystems, herbicides are sometimes used to reduce the density of exotic or invasive weed species and thus indirectly increase the diversity of native or desirable species. Where herbicides inadvertently enter the environment as contaminants, detrimental impacts on nontarget plants and other organisms may occur. However, the threat to plant biodiversity caused by habitat loss and the spread of exotic species is far greater than that caused by all forms of environmental pollution, including herbicides. This article reviews concepts of weeds; principles of weed management; and categories, action, and fate of herbicides. Impacts of herbicides on biodiversity of both target (weeds) and nontarget species and the role of weed control in preserving biodiversity are also discussed.

The Concept of a Weed

Weeds are most often defined in human or anthropomorphic terms, that is, as plants growing where they are not wanted or plants out of place. More useful definitions of weeds are those that describe biological traits or characteristics. A list of “ideal characteristics of weeds,” developed by Baker (1974), is widely known and cited for its description of traits that confer weediness on plants that possess them (Table 1). These traits include germination under a broad range of conditions and over an extended period; rapid growth and prolific reproduction by sexual and asexual means; flexible breeding systems including selfpollination, cross-pollination, and

nonspecialized pollinators; effective seed dispersal; plasticity and tolerance of a breadth of environmental conditions; and adaptations for competitiveness. Though no plant species could possess all of these traits, plants considered to be major weeds are likely to possess many of them. Traits alone do not determine whether a plant will be a weed, but Baker’s list is a useful tool for categorizing and studying plants that interfere with human activities and, thus, are called weeds.

Impacts of Weeds

By their very definition, weeds affect many activities in which humans are engaged. In agroecosystems their primary effect is

Table 1 Characteristics of the “Ideal Weed”

Germination requirements fulfilled in many environments
Discontinuous germination (internally controlled) and great longevity of seed
Rapid growth through vegetative phase to flowering
Continuous seed production for as long as growing conditions permit
Selfcompatible but not completely autogamous or apomictic
When cross-pollinated, unspecialized visitors or wind utilized
Very high seed output in favorable environmental circumstances
Produces some seed in wide range of environmental conditions; tolerant and plastic
Has adaptations for short- and long-distance dispersal
If a perennial, has vigorous vegetative reproduction or regeneration from fragments
If a perennial, has brittleness, so not easily drawn from ground
Has ability to compete interspecifically by special means (rosette, choking growth, allelochemicals)

Source: Reproduced from Baker HG (1974) The evolution of weeds. *Annual Review of Ecology and Systematics* 5: 1–24, with permission from Annual Reviews.

to reduce crop yield and quality through competition for limited resources. Weeds also increase the time and costs required for crop production and interfere with harvesting. Indirectly, weeds affect crops through both positive and negative interactions with insect herbivores and their natural enemies. In rangelands, weeds possessing thorns or barbs pose physical hazards to livestock, and those containing toxins may cause allergies or poisonings of animals or humans. Other negative impacts of weeds include obstructing visibility around roadways, serving as a fire hazard, impeding use of recreation areas, and blocking the free flow of water in waterways, irrigation canals, and drainage ditches. In nonagricultural ecosystems, weeds often comprise the first stage of plant succession on land where the native vegetation has been disturbed. With increasing movement of humans across continental boundaries, exotic (non-native) weed species have invaded many wildland ecosystems where human activities have disrupted the growth of indigenous (native) species. As a result, biological diversity has been reduced in many wildland areas that interface with urban areas. Other impacts of weed invasions in wildlands include alteration of ecosystem processes, support of non-native animals, fungi, or microbes, and hybridization with native species to alter gene pools (Radosevich *et al.*, 2007).

Weed Science

Since the beginning of agriculture, humans have employed various tactics to remove weeds from land where other uses are desired. In the US today, billions of dollars are spent annually for weed removal using chemical and mechanical means. With the discovery of synthetic organic herbicides in 1941, weed science developed as a formal scientific discipline (Anderson, 2007). Weed scientists have been extremely successful during this century in developing techniques to remove weeds from agricultural and other ecosystems. Over the past 50 years, weed science has grown into a multidisciplinary field of study encompassing fundamental research along with applied aspects of weed suppression. Today it encompasses researchers from numerous scientific disciplines, including chemistry, ecology, genetics, morphology, and physiology, as well as applied scientists and practitioners who focus on weed suppression (Radosevich *et al.*, 2007). In recent years, increased awareness of environmental concerns has shifted the emphasis in weed science from a primary focus on herbicides to more integrated, ecological approaches for dealing with weeds (Liebman *et al.*, 2001).

Weed Management

In crop, forest, and rangeland production systems, as well as in wildlands, weed presence must usually be minimized to achieve a desired land use goal. Various tools and methods are used to suppress or remove weeds while not injuring the crop or desirable species. Weed management is a strategy that includes growing or fostering desired or beneficial vegetation while suppressing unwanted plants. For such management to be successful, knowledge of the biology, ecology,

life history, and taxonomy of the weed species is required, as well as selection of the proper tools to use for their suppression (Clout and Williams, 2009; Radosevich *et al.*, 2007).

Tools and Methods of Weed Management

The strategy of weed management includes three key components: prevention, eradication, and control (Ross and Lembi, 2009). Prevention is keeping a weed from being introduced into an area where it does not already occur. Common preventive measures include using sanitary practices, eliminating weed spread through seeds and vegetative propagules, using quarantines, and following federal and state weed laws and regulations. Eradication is the total elimination, from a particular area, of a weed species and any plant parts capable of reproducing. Although eradication is often a stated goal of weed management programs, it is seldom achieved owing to the presence of seed banks and vegetative bud reserves in the soil of weed-infested areas. In contrast to eradication, weed control is the suppression or reduction of a weed species to an economically acceptable level. Under weed control programs, complete elimination of the weed is not the goal; instead, weeds are reduced to a level at which the cost of continued suppression does not exceed the value of the land or crop growing on it plus the benefit afforded by weed control. Once a weed is established in an area, weed control is the approach most commonly used to manage vegetation in that area over the long term. Methods used for weed control include biological, chemical, cultural, and mechanical techniques.

Integrated Approaches to Weed Management

With the growing recognition and concerns about the environmental impacts of agricultural practices, particularly the use of herbicides, integrated approaches for weed management have become commonplace. Integrated weed management (IWM) refers to a strategy for weed suppression that combines information on the biology and ecology of the weed with all available control technologies. Using this strategy, a variety of different methods are used in weed control, including nonchemical ones, as well as preventive measures, such that emphasis on herbicides is minimized. An alternative approach to crop production that is currently receiving widespread attention is sustainable agriculture, which refers to production systems in which external inputs, including synthetic fertilizers and pesticides, are minimized or avoided. However, current knowledge about the biology and ecology of weeds, their interactions with crops and wild plants, and nonchemical methods for their control is still limited. Thus, in most agricultural systems today, achieving weed control without herbicides requires extensive mechanical and hand labor, which is very costly. Until viable and economical alternatives to herbicides are available, most crop production and land management systems in the US will continue to depend on some level of herbicide use for weed control (Ross and Lembi, 2009).

Chemical Weed Control

Herbicides are chemicals used to suppress or kill plants or to interrupt their normal growth processes (Cobb and Reade, 2010). Of all groups of pesticides (including insecticides, fungicides, and rodenticides), herbicides are the leading group in terms of tons produced, dollar value from sales, and total acreage treated. Extensive and widespread use of herbicides in agriculture continues because of their high level of effectiveness and low cost relative to other methods of weed control. Use of herbicides has resulted in improved control of weeds that grow within crop rows where cultivation is not possible. Herbicides have replaced frequent tillage operations in some systems, which conserve energy, reduce crop damage, and minimize damage to soil structure. With herbicides, crop production is less dependent on weather and human labor, such that greater flexibility in choice of crops and management methods is possible. In the US today, the abundance of relatively inexpensive food and fiber is due in large part to the benefits afforded by herbicides for weed control in the last half century. However, the use of herbicides also carries risks, including injury to crops and nontarget plants, herbicide residues in soil or water, toxicity to nontarget organisms, and concerns for human health and safety. For this reason, the benefits and risks of each method must be weighed carefully when developing a weed control program, particularly in wildland ecosystems. In the US, all pesticide development and use is subject to strict regulation by the federal government.

Herbicides

There are approximately 150 herbicide active ingredients, which are formulated into hundreds of commercial products (Senseman, 2007). Most are organic compounds, containing carbon, hydrogen, oxygen, and various other chemical elements. Each herbicide has a chemical name that describes its structure and a common name, which is often a simplified version of the chemical name. Formulated herbicides also have a trade name assigned by the manufacturer for marketing purposes. Manufacturers formulate herbicides to enhance their handling and weed control properties. Formulated compounds include the herbicide active ingredient plus inert ingredients such as solvents, diluents, and various additives. When the same herbicide active ingredient is formulated in more than one way, each is assigned a different trade name. Herbicides can be classified in several different ways, which provide users with a convenient means of selecting herbicides for various purposes.

Herbicides are often classified according to similarities in chemical structure, which often, but not always, result in similar effects on plants. A more useful classification scheme is based on where they may be used. In agriculture, herbicides are registered for use in agronomic and horticultural crops, turfgrass, and landscape and ornamental plantings. In non-crop areas, herbicides are used in pastures and rangelands, aquatic habitats, rights-of-way, utility sites, recreation areas, forests, and wildlands. Herbicides are also classified according to the method and timing of application. Application methods include soil and foliage treatments, depending on where in the plant the chemical is most readily absorbed. Timings of herbicide application include preplant (prior to crop

planting), preemergence (prior to crop or weed emergence), and postemergence (after crop or weed emergence). A herbicide classification scheme based on method of application is summarized in Table 2.

Other classification schemes are based on plant responses to herbicides. Selective herbicides are more toxic to some plant species than others (e.g., monocotyledonous vs. dicotyledonous plants), whereas nonselective herbicides are toxic to all plant species. Selectivity is one of the most important and useful characteristics of herbicides, for it allows applications to be made to weeds without the risk of injury to crops or desirable vegetation. Factors related to herbicide chemistry (structure, formulation), the plant (age, size, surface characteristics, morphology, physiology), and the environment (humidity, temperature, soil moisture) determine the selectivity of a particular herbicide. Other categories of plant response used to classify herbicides are the pathway of herbicide movement in plants and the mechanisms by which herbicides kill plants (see Table 2). Systemic herbicides are those that move in plants; movement occurs in the phloem (sympplast), xylem (apoplast), or both. Herbicides that do not move in plants, but rather exert their effect at the site of application, are called contact herbicides. Herbicides classified by mechanism of action include growth regulators; inhibitors of photosynthesis, pigments, lipid synthesis, cell wall synthesis, amino acid synthesis, and cell division; and cell membrane destroyers.

Fate of Herbicides in the Environment

Herbicide fate in the environment is an issue of public concern and an important consideration when herbicides are registered for legal use. For herbicides to be effective, they must persist long enough to kill the weeds for which they were intended. Persistence beyond that time, however, may result in injury to nontarget plants and other organisms, residues in crops, and environmental contamination. Herbicides that enter plants generally move to a site of action and cause a toxic reaction. Over time, most herbicides in plants are transformed into relatively less toxic forms by biochemical processes. If a herbicide is not degraded, it may remain in the plant or end up in the soil as a contaminant. Eventually, however, all herbicides that enter a plant, the soil, water, or atmosphere will be degraded by the same chemical and physical reactions that act on biologically derived compounds (Cobb and Reade, 2010).

Once a herbicide reaches the soil, several processes, including adsorption to soil particles, movement to another location, and decomposition, will determine its persistence. Soil and herbicide characteristics regulate adsorption of herbicide molecules onto particles of clay and organic matter. Herbicides that are tightly adsorbed are not available for plant uptake, movement to other sites, or decomposition. Herbicides that are loosely adsorbed or located in the soil solution may move by leaching (vertical and lateral movement by water). The potential for movement of herbicides into groundwater through leaching is a concern for a few very mobile herbicides, which consequently are subjected to strict monitoring and regulation. Herbicides may also enter the environment during application by drift (movement of herbicide particles in air) or from the soil surface by

Table 2 Herbicide classification according to the method of application, movement in plants, and mode of action (examples of herbicide classes or individual herbicides in each category are listed)

<i>Method of application</i>	<i>Movement in plants</i>	<i>Mode of action</i>	<i>Chemical class or individual herbicide</i>
Foliar	Translocated in phloem	Auxin-type growth regulators	Phenoxy acid, benzoic acid, and picolinic acid herbicides; naptalam
		Aromatic amino acid (EPSPS) inhibitors	Glyphosate
		Branched-chain amino acid (ALA/AHAS) inhibitors	Sulfonylurea, imidazolinone, pyrimidinyl oxybenzoate, and triazolopyrimidine sulfonanilide herbicides
		Carotenoid pigment inhibitors	Amitrole, clomazone, fluridone, isoxaflutole, norflurazon
		Lipid biosynthesis (ACCase) inhibitors	Aryloxyphenoxy propionate and cyclohexanedione herbicides
Foliar	Translocated in xylem	Organic arsenicals	DSMA, MSMA
		Unclassified herbicides	Asulam, difenzoquat, fosamine, propanil
		Photosystem II (PSII) photosynthetic inhibitors	s-Triazine, phenylurea, and uracil herbicides; metribuzin
Foliar	Contact (not translocated)	Other photosynthetic inhibitors	Phenylcarbamate herbicides, bentazon, bromoxynil, pyrazon, pyridate,
		Photosystem I (PSI) cell membrane destroyers	Bipyridilium herbicides
		Protoporphyrinogen oxidase inhibitors	Diphenylether, oxadiazole, and triazolinone herbicides; flumiclorac
Soil	Depends on herbicide	Glutamine synthesis inhibitors	Glufosinate
		Microtubule/spindle apparatus inhibitors (root inhibitors)	Dinitroaniline herbicides; DCPA, dithiopyr, pronamide
		Shoot inhibitors	Chloroacetamide and thiocarbamate herbicides
		Miscellaneous cell division inhibitors	Bensulide, napropamide, siduron
		Cell wall formation inhibitors	Dichlobenil, isoxaben, quinclorac

Abbreviations: EPSPS, 5-enolpyruvylshikimate-3-phosphate synthase; ALS, acetolactate synthase; AHAS, acetohydroxy acid synthase; ACCase, acetyl-coenzyme A carboxylase; DSMA, disodium methanearsonate; MSMA, monosodium methanearsonate; DCPA, dimethyl 2,3,5,6-tetrachloro-1,4-benzenedicarboxylate.

volatilization (conversion into a vapor). Both of these processes can be minimized or avoided when proper equipment and application techniques are used.

Herbicide decomposition occurs in soil, air, water, plants, animals, and microorganisms and results in breakdown of the original herbicide molecule and loss of herbicide activity. Decomposition of herbicides occurs by photochemical (breakdown in sunlight), chemical, or microbiological means. Herbicide decomposition also depends on temperature and other environmental factors, plus the concentration of herbicide applied. Products of herbicide decomposition may eventually degrade into simple organic molecules. Because most herbicides are degradable, they do not build up in the soil over time, even after repeated use. Additionally, the soil microbial populations are adaptable such that the application of a pesticide to soil is often followed by an increase in the number of microbes that can degrade it. When processes that regulate herbicide fate are understood, and the legal requirements for herbicide application and use are followed, minimal contamination of the environment should result.

Regulation of Herbicide Use

All pesticides, including herbicides, must be registered with the U.S. Environmental Protection Agency (EPA) before they can be distributed or sold in the US (Whitford, 2002). Two

laws, the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), and parts of the Food, Drug, and Cosmetic Act (FDCA) regulate pesticide development and use. FIFRA provides for registration and cancellation of pesticides, maintains a classification system for pesticides based on toxicity, and allows states to regulate pesticide use in a manner consistent with federal regulations. The FDCA mandates the establishment of tolerances for pesticides in food, feed, fiber, and water. These laws were written to ensure that benefits from the use of pesticides are in balance with the concerns about health and environmental impacts. Each state also has laws regulating pesticide use, including worker safety regulations and requirements for use of the most toxic (restricted use) pesticides.

For a pesticide to be registered by the EPA, it must be subjected to over 100 safety and environmental tests. Information required before registration includes chemical and physical properties, environmental fate, amounts of the pesticide in feed and food crops, toxicological properties, and effects on nontarget plants and animals. Such data are usually required both for the pesticide and for its metabolites, or breakdown products. With this information, the relative benefits and risks of each pesticide can be determined.

Pesticide effects on human health are expressed as toxicity, the amount of the chemical that is harmful or lethal, and exposure, the probability of encountering a harmful dose of

the chemical. The combination of acute toxicity plus exposure to a pesticide during its expected use determines the hazard it poses to humans. The EPA uses these data to set a tolerance level for each agricultural pesticide, which is the maximum amount of the chemical allowed on a particular crop. These and many other data, including chronic toxicity, reproductive effects, teratogenicity, and carcinogenicity, are used by the EPA in setting limits for pesticide use to ensure that hazard to humans from the use of pesticides will be at acceptably low levels. Toxicology and exposure studies are also required on certain species of wildlife, including birds, fish, and invertebrates, before pesticides can be registered. These tests utilize studies of pesticide residues in foods that these species may consume, as well as potential concentrations of pesticides in water or air to determine hazard to nontarget species from pesticide use.

Pesticides vary widely in their toxicological properties. In relation to all pesticides, which include insecticides, fungicides, and rodenticides, most herbicides are relatively nontoxic to mammals, since many of the processes or pathways they inhibit in plants are not present in mammalian systems. For the purposes of regulation, pesticides are classified according to their toxicity, which is a relative term used to describe the amount of a chemical that causes harm to a particular species. The most common unit of measurement for toxicity is the lethal dose, LD₅₀, or lethal concentration, LC₅₀, which is the dose or concentration that kills 50% of the test population, respectively. High values for LD₅₀ or LC₅₀ indicate lower toxicity, as higher doses are required to produce lethal effects. The categories of acute toxicity that must be shown on herbicide labels are listed in Table 3. Because all herbicides are toxic to some degree, container labels are required to give specific directions for-use as well as ingredients, properties, hazards, exposure limits, first aid procedures, and other information. When handled according to the label directions, hazard to humans and wildlife from exposure to herbicides can be avoided.

Effects of Herbicides on Biodiversity

Weeds

All weed control practices exert selection pressure on weeds and thus can have short- and long-term effects on the composition, structure, and dynamics of weed communities (Radosevich *et al.*, 2007). Agricultural weed communities tend to have lower species diversity than natural plant communities and are often dominated by a few key species. The primary short-term effect of weed control is a reduction in weed

density, particularly of the dominant species, which is desirable in order to improve crop yields or facilitate land use. Over a longer time frame, weed control practices rarely eliminate weeds altogether; rather they generally result in changes in species composition and structure of weed communities. In the case of herbicides that act on specific plant processes, selection pressure over time can eliminate susceptible genotypes and thus cause evolutionary changes in weed populations.

Most research in weed control to date has emphasized reducing weed density and improving crop yields. Only recently the attention has been focused on changes in weed community dynamics as a result of weed control practices. Thus, only a few generalities can be made about specific effects or directions of change in weed diversity caused by biological, cultural, mechanical, and even chemical methods of control. The most information available on the role of weed control in shaping weed communities comes from documented cases of herbicide-resistant weeds, which have been selected by repeated use of the same herbicide or herbicide group (Powles and Holtum, 1994). It is clear that herbicides are a powerful evolutionary force acting on weed community composition. However, herbicide effects on weed diversity are generally transient and occur immediately following application. Over longer time periods, herbicide effects on weed diversity are either inconsistent or not apparent, and in many cases are overshadowed by more pronounced effects of other weed control and cropping practices.

Effects of Weed Control Practices

Changes in weed community composition and structure due to agricultural practices have been documented; however, assessments of the effects of these practices on weed species diversity are relatively limited. Clements *et al.* (1994) calculated diversity indices from an array of published data to compare the impacts of conventional and alternative weed management practices on weed species diversity. When compared to weed control by mechanical cultivation only, broadcast applications of herbicides resulted in lower weed species diversity over time. When herbicide use was reduced by placement of applications only in bands over the crop row, higher diversity of weeds resulted than when broadcast herbicide applications were made. Although these findings suggest that use of herbicides reduces weed species diversity, case studies show that this generalization is too simplistic. Impacts on diversity depend on several factors, including the periodicity of tillage practices, weed species susceptibility to the herbicide product and rate (dosage), and variability in weather and its interaction with herbicide efficacy (Grundy *et al.*, 2010). When different herbicides were evaluated, in some cases applications of pre-emergence herbicides (those having residual soil activity) reduced weed species diversity more than the applications of postemergence herbicides (those with no residual activity). By exerting continuous selection pressure on susceptible species from the time of emergence, pre-emergence herbicides can reduce the richness and diversity of weed communities. In contrast, post-emergence herbicides are present in the environment only after emergence and for a shorter time period, which may permit a more diverse weed flora to establish both before and after the disturbance of herbicide application is imposed.

Table 3 Toxicity, signal words, and lethal dosages (LD) used in herbicide labeling

Toxicity	Signal word	Oral LD ₅₀ (mg/kg)	Dermal LD ₅₀ (mg/kg)
Very high	Danger	≤50	≤200
High	Warning	51–500	201–2000
Moderate to low	Caution	>500	>2000

Potts *et al.* (2010) monitored changes in the weed flora of cereal crops in England over 38 years and documented persistence and stability of weed abundance over time. Short-term decreases in weed abundance occurred following the use of herbicides and long-term changes in species composition were observed, including a steady increase in the abundance of perennial dicotyledonous (dicot) species. However, other agricultural practices were more important drivers of these long-term changes in species composition than were herbicides. Weed diversity increased over the monitoring period, possibly due to the buffering effect of the soil seed bank.

Even in cases where weed species diversity is relatively unaffected by herbicide applications, however, interspecific selectivity of many herbicides causes a shift within a weed community from species that are susceptible to species, that are naturally more tolerant, to the particular herbicide. A common example of this phenomenon is the shift in relative abundance from dicot weed species to monocotyledonous (monocot, usually grass) weed species following repeated use of the herbicide 2,4-D for control of dicot weeds in cereal (grass) crops. Similarly, in fields where herbicides have been used over many years for control of annual weed species, shifts in the weed flora to predominantly perennial weed species are commonly observed. Weed species compositional shifts also occur when the weeds in a field are taxonomically related to the crop species grown there, since plants often respond similarly to herbicides when they are in the same taxonomic family. Thus, many cases have been documented where repeated use of a particular herbicide in a crop has selected for weeds that are in the same plant family as the crop.

Integrated and alternative weed management methods, which employ a combination of tools to control weeds below a specified threshold, theoretically should not impose strong directional selection on weed populations. Thus, weed species diversity might be expected to increase, decrease, or remain stable, depending on the combination, timing, and frequency of control methods used. Similarly when control methods are rotated or changed over time, selection of well adapted or less susceptible weed biotypes is minimized. Many questions remain to be answered about the potential effects of integrated weed management techniques on diversity of weeds. In addition, the role and potential importance of weed biodiversity in agroecosystems remain poorly understood.

Selection of Herbicide Resistance

Herbicide resistance represents an extreme shift in weed species composition caused by the selection of plants possessing a gene or genes for resistance to a particular herbicide within a species that was formerly susceptible (Powles and Holtum 1994). In cases where a particular herbicide has been used repeatedly over several years, resistant weeds may be selected and come to dominate a weed community such that species diversity declines. Since the 1970s, many cases of the evolution of resistance have been documented as a result of repeated herbicide applications for weed control. Table 4 summarizes the current worldwide occurrence of resistant weed biotypes to different herbicide groups.

Several characteristics of herbicides and their use contribute to a high probability for selection of resistance in weeds. These include having a single target site and specific

Table 4 Worldwide occurrence of resistant weed biotypes to different herbicide classes

mechanism of action, being extremely active and effective in killing a wide range of weed species, and having long soil residual activity and season-long control of germinating weeds. In addition, frequent application of a particular herbicide over several growing seasons without rotating, alternating, or combining with other types of herbicides contributes to a high risk for the evolution of resistance. Some herbicides are thought to pose a low risk for selection of resistance owing to their nonspecific mechanism of action and short or no soil residual activity. Even in these cases, however, repeated use of the same herbicide will exert selection pressure on weeds. Recommendations for preventing or managing herbicide-resistant weeds include practices such as rotating herbicides from different chemical groups to avoid imposing the same selection pressure over time and integrating a combination of weed control methods. The higher level of weed species diversity that presumably would result from these approaches should reduce the potential for propagation of herbicide-resistant genes in weed populations.

Since the discovery of evolved resistance to herbicides in the 1970s and the concurrent advancement of molecular technology, many crops have been genetically engineered for desirable traits, including resistance to herbicides. Transgenic herbicide-resistant crops, particularly cotton, maize, and soybean are now widely grown in the US (Owen, 2008). When this technology was first adopted, one concern was the potential for reliance on a single herbicide to which the crop was resistant and subsequent selection of weeds that are not

susceptible to that herbicide. Research conducted to date has shown that herbicide-resistance in crops has a benign effect on weed abundance and diversity. Instead, it is the weed control methods, including herbicides, as well as other management practices used in those crops that exert selection pressure for changes in weed abundance, composition, and dynamics, as discussed above.

Other Organisms

By suppressing, removing, or destroying vegetation, weed control modifies the environment and habitat of other organisms. In agroecosystems, crop pests as well as beneficial organisms can be affected by weed removal since weeds can serve as host plants or food sources for many types of organisms, including insects, fungi, and nematodes (Norris and Kogan, 2000). In some cases, a high diversity of weed species in an agricultural field has been shown to reduce the magnitude of insect attacks on crop plants because the weeds serve as alternate food for the insect pests or harbor beneficial organisms that feed on the pests. In other cases, however, increased weed species diversity results in increased insect problems in a crop field because the weeds provide a food source or habitat so that the insect pest can remain in the field even during periods when the crop is absent. In those cases, weed control to reduce the diversity of weeds in a particular field will decrease the incidence of insect pest damage to the crop, to the extent that herbicides affect weed biodiversity, therefore, their use will also indirectly affect insect organisms.

The response of fungal and nematode populations to weed species diversity has not been well studied. In general, weed control practices result in a cleaner crop field, which usually leads to fewer disease and nematode problems. However, it is also possible that large areas of crop monocultures with few weeds may be susceptible to widespread disease epidemics because of the lack of genetic diversity in response to the disease. To date, little information is available to indicate how weed biodiversity or use of herbicides in weed control influence populations of fungal pathogens or nematode pests of crop plants.

As noted above, most herbicides are nontoxic to mammals, which lack most of the biochemical pathways in plants that are targeted by herbicides. Aside from toxicology research required for registration, studies of herbicide effects on animals in field settings are limited. One exception is aquatic communities, which have been relatively well studied since taxon diversity is usually high and pesticides can move more readily than in terrestrial ecosystems. As expected, impacts on animals are pesticide specific. While some insecticides have direct negative impacts on aquatic animals, such as zooplankton, insects, amphibians and others, any negative herbicide effects are generally indirect through a reduction in food or shelter for organisms at higher trophic levels. One study showed direct negative effects on tadpoles of glyphosate herbicide when it was formulated with a surfactant additive; however, this additive is absent in the aquatic forms of the herbicide, which had no detrimental effects on tadpoles or other animals (Relyea, 2005). Thus, in both terrestrial and aquatic ecosystems, herbicides used properly appear to have only indirect

effects on nonplant organisms when weeds they rely on for food, habitat, or other uses are controlled.

The question whether weed biodiversity is an asset or a detriment to overall pest management and other ecosystem services in agriculture deserves serious attention by researchers. This issue is particularly important in the UK and other countries where the majority of land is agricultural and wilderness areas are limited. In some regions weeds are increasingly being considered an important component of healthy agroecosystems and worthy of conservation (Marshall *et al.*, 2003). Evidence exists showing that agricultural intensification over the past century, including use of herbicides and inorganic fertilizers, has been accompanied by a reduction in populations of many insect groups and birds, presumably through reductions in weeds that they rely on (Storkey and Westbury, 2007). To understand the importance of weed biodiversity in agroecosystems, more information is needed on the effects of various weed control practices on both weed biodiversity and nonweed organisms. With this information, the costs and benefits of weed control can be weighed against potential costs and benefits of alternative strategies to other organisms that are indirectly affected by weed control. The question is complicated by the fact that in large-scale mechanized agricultural production, increases in weed species diversity complicate weed control efforts. However, this problem could be offset if there were benefits to be gained from maintaining increased genetic diversity of weeds in a field, such as greater buffering against selection for herbicide resistance, enhanced pest control, improved nutrient cycling, or other ecosystem services.

In wildland situations where exotic weeds have replaced native vegetation, weed control is increasingly practiced to reduce weed invasions and restore the abundance and diversity of native plants. The indirect result of these weed control activities is often a restoration of habitat for nonplant organisms, such as birds and small mammals. In these situations, therefore, weed control, including use of herbicides, can result in increased diversity of other organisms that depend on native plant communities for habitat.

Wild Plants

Weeds are managed in many situations to restore or preserve the biodiversity of native plant species. The most common methods used for weed management in wildlands in the US are manual and mechanical weed removal, prescribed fire, release of biological control agents, use of grazing animals, encouragement of native competitors, and judicious use of herbicides (Clout and Williams, 2009). Weed management strategies in wildlands differ from those in agroecosystems because wildland managers must promote or protect large numbers of plant and nonplant species rather than one or a few crop species. Thus, wildland weed management is generally approached with a desire to manage an entire plant community rather than to control a single weed species. Although the same methods can be used in agricultural and nonagricultural habitats, wildland managers must minimize negative impacts to a wider range of nontarget species than must agricultural land managers. Therefore, the methods used

for wildland weed control are often labor-intensive and more environmentally conservative than in agroecosystems.

All weed control methods incur some risk to the environment in which they are used, which must be weighed against the risk of taking no action and allowing weeds to continue to spread. Mechanical weed control disturbs the soil, destroys vegetation, and leaves gaps that may be reinfested with weeds. Biological control agents may attack nontarget species or become adapted and spread in undesirable ways. Herbicides may unintentionally kill nontarget plant species, indirectly impacting habitat for other organisms, and may become environmental contaminants if not used properly. In most cases, the herbicides used in wildland situations are postemergence compounds with very short or no soil residual activity to minimize their effect on nontarget plant species. However, few empirical data exist on either intentional or unintentional effects of herbicides on native plant communities.

A long-term field study on the effects of herbicides on the structure and species diversity of native plant communities showed that herbicide treatments were highly effective in controlling the exotic weed (*Centaurea maculosa*, spotted knapweed) and converting the plant community back to its native composition (Rice *et al.*, 1997). Overall, only small, short-term depressions in species richness and diversity resulted from herbicide use. In another field study comparing various methods of removing an invasive grass (*Microstegium vimineum*, Japanese stiltgrass), native community diversity was over 20% greater following either hand-weeding or post-emergence herbicide use as compared to nontreated plots, indicating that the invasion was suppressing the native plant community (Flory and Clay, 2009). As shown in agroecosystems and as discussed earlier, however, the rate, frequency, and timing of herbicide applications are important determinants of plant community responses. Higher rates, more frequent applications, or applications early in the growing season have been shown to reduce the diversity of nontarget species more than lower rates, less frequent applications, or later applications. Similarly, selectivity of the herbicide as well as precision of the application method can be managed to reduce the impacts on nontarget species. These and other studies show that periodic application of appropriate herbicides can be used to restore native plant communities from dominance by exotic species and to maintain their diversity, as well. Transient reductions in diversity that may result from herbicide use are likely to be negligible when compared to the serious impacts on native communities created by exotic plant species.

As in agroecosystems, questions remain in natural systems about the role and management of weed abundance and diversity in wildland ecosystems. Where exotic weed invasions are widespread, weed removal alone may not result in the establishment of native species without additional inputs such as revegetation with desirable species. In some areas, invasive exotic weeds have replaced native species and become an important source of food and cover for native birds and mammals, which must be considered before the weeds are removed. The use of herbicides in wildlands is often controversial because of the risks of environmental contamination, as well as the general public perception that herbicides are dangerous. Just as in agriculture, therefore, the costs and benefits of weed control in wildlands must be weighed before

any method is chosen. In cases where herbicides are used, the determination is made that the risks of using herbicides are more than the offset by the benefits gained in the increased or restored diversity of native species due to control of exotic weeds.

Conclusions

Herbicides have been employed for decades to control unwanted vegetation in agroecosystems, yet their impacts on weed biodiversity and the implications of those impacts for weed management have not been well studied except in the case of the evolution of herbicide resistance. Increasing emphasis over the past decade on the importance of maintaining diversity of all genetic resources has rarely been extended to agroecosystems, despite the likelihood that assessments of the nature and importance of weed biodiversity might reveal an important role of weeds in agroecosystem stability and sustainability. Based on experiences with herbicide use in agriculture, deliberate use of herbicides to control invasive weed species in wildlands has become increasingly common, yet the impacts of herbicides on the composition, structure, and dynamics of nontarget native plant communities are poorly understood and usually assumed to be negative. When placed in a comparative context, however, habitat degradation and destruction, particularly by competition with exotic species, is a much more pervasive threat to biodiversity of the endangered plant species than is pollution of all forms, including agricultural pesticides. Thus, it is imperative that research be continued into the effects of all forms of weed control on biodiversity of both target and nontarget species.

Glossary

Allopolyploid Species with chromosome sets derived from interspecific hybridization and chromosome doubling.

Hybrid An individual that results from crossing between individuals from two or more populations, races, subspecies, species, etc., including individuals that are F1s, F2s, and the set of all backcrosses.

Hybridization Interbreeding of individuals from two or more populations of species, subspecies, or races.

Hybrid swarm Mixture of hybrid genotypes, including F1s, F2s, and backcrosses, due to hybridization between two or more species that co-occur in a locality.

Hybrid zone Area of overlap or point of contact between two populations that are distinguishable based on one or more heritable characters where viable or partially fertile hybrids are formed.

Introgression Permanent transfer of genes from one or more species, subspecies, or race into another species, subspecies, or race via hybridization and backcrossing.

Reticulate evolution Pattern of speciation where new species arise from interspecific hybridization between two species coupled with establishment of reproductive isolation.

Introduction

Despite common use of the term “hybridization” in plant biology, application of the term varies widely. To some, hybridization involves crossing between two species and the production of fertile offspring (although fertile progeny are not required in all definitions). At the opposite end of the genetic spectrum, hybridization may refer to crossing between any two individuals, as opposed to self-fertilization. Still others recognize the intergradation, and sometimes arbitrary distinction, between differentiated populations, races, subspecies, and species and therefore consider hybridization to occur when individuals of differentiated populations or population systems interbreed (see Arnold, 1997; Levin, 2002). These definitions are not merely semantic differences – they have implications for our understanding of the frequency, genetics, and ultimate role of hybridization in generating, or eroding, biodiversity. In this article, interactions between species are focused, with the understanding that species represent an arbitrary level of the biological hierarchy and that species limits are not always clear.

Hybridization has variously been viewed as an engine of biodiversity (Arnold, 1997, 2004; Anderson and Stebbins, 1954) and as evolutionary noise (Stebbins, 1971; Wagner, 1970), and it is likely both in different circumstances. Rare hybridization between two largely allopatric species may have little or no long-term effect on the gene pool of either species, particularly if the hybrids are sterile; and this scenario, which is probably quite common, clearly represents evolutionary noise. In contrast, hybridization, particularly when coupled with polyploidy (genome doubling; whole-genome duplication (WGD)), results in speciation, with the generation of novel phenotypes that occupy novel niches (see Soltis and Soltis, 2009). In this article, an overview of the varying extent

of hybridization and its associated evolutionary consequences has been provided, with an emphasis first on homoploid hybridization (i.e., hybridization involving species of the same ploidy, typically both diploids) and then on polyploidy and hybridization.

Homoploid Hybridization

Hybridization between two species may have little or no impact on either species in either the short or long term. However, hybridization may have evolutionarily significant consequences for the participating species, ranging from small genetic exchanges to the origin of species.

Introgression

Introgression – the transfer of genetic material between species following hybridization and backcrossing to the parental species – is a fundamental concept of plant evolutionary biology (Anderson and Hubricht, 1938; Anderson, 1949). However, it is difficult to demonstrate in natural populations, and its extent in nature is therefore unknown. The elegant treatment of the topic by Anderson (1949), coupled with painstakingly described morphological variation in key groups of plants (e.g., Heiser (1949) on sunflowers), led botanists for many years to believe that introgression played a significant role in plant evolution. However, later perspectives on the difficulty of distinguishing between “primary intergradation” (i.e., divergence of a population system into two species) and “secondary intergradation” (hybridization; e.g., Mayr, 1942), along with limited genetic markers for actually testing for hybridization, led many botanists to question how common hybridization and introgression really were.

Then along came deoxyribonucleic acid (DNA) markers, especially the chloroplast genome (cpDNA). In the 1980s, cpDNA restriction site markers were being applied to studies of plant phylogeny. These markers were ideal for reconstructing the evolutionary history of closely related species (e.g., Palmer *et al.*, 1985), such as those classified in the same genus, and tremendous progress was achieved in plant systematics in a very short time. However, these studies did more than clarify relationships among plant species: they also showed the underlying history of interspecific hybridization.

In many plant groups (e.g., *Salix*, willows; Brunsfeld *et al.*, 1992), instances arose where populations of a morphologically uniform species did not appear to be monophyletic (i.e., descended from a single common ancestor) in the phylogenetic trees derived from cpDNA data. Typically, one population, which occurred sympatrically with another species, had the cpDNA of the sympatric species rather than its “own” cpDNA. This phenomenon, termed chloroplast capture (Rieseberg and Soltis, 1991), resulted from hybridization between two species, followed by continued backcrossing to the paternal parent to yield a population with the nuclear genotype – and therefore general phenotype – of one species and the cpDNA (which is maternally inherited) of the other, in other words, introgression of the cpDNA of one species into the other species. Despite the seemingly low probability of these events occurring, hundreds of cases of chloroplast capture have been reported, making chloroplast introgression one of the most common – and significant – outcomes of hybridization.

Novel Genotypes Through Hybridization and Introgression

Introgression, whether of nuclear genes or cpDNAs, provides the opportunity to generate novel genetic combinations on which selection can act. Classic models of hybridization and introgression argue that a hybrid or introgressant requires a novel “hybridized” habitat if it is to survive – it simply cannot compete with its established parents in either of their habitats. For this reason, offspring of hybridization and introgression are predicted to occur (and often do; Stebbins, 1985; Bayer *et al.*, 1991) in habitats that are intermediate between those of its parents.

This sort of novelty is perhaps best seen in several hybrid species of sunflowers. *Helianthus annuus*, the common sunflower, has hybridized extensively with other species of *Helianthus*, and on multiple occasions hybridization has led to species formation (Rieseberg 2006; see Hybrid Speciation). One hybrid species, *Helianthus anomalus*, occurs on sand dunes in the deserts of the southwestern USA, an extreme habitat that is differentiated from the prairie habitats of both parents (Rieseberg *et al.*, 2007). Likewise, *Helianthus paradoxus* occupies extremely saline environments, a novel habitat perhaps conquerable because of the genetic novelty of the hybrid genotype (Rieseberg *et al.*, 2007).

Certainly, genetic mechanisms for hybrid novelty can be proposed, such as combinations of genes that yield “hybrid vigor” or heterosis. In addition, novel alleles may be generated from the parental copies through recombination, such that half of an allele may be contributed by one parent and the

other half from the second parent (Golding and Strobeck, 1983). Although rare, such mutations may generate the types of genetic combinations that lead to morphological and physiological novelty.

The origin of genetic novelty in hybrids or introgressants may not be limited to the nuclear genome. Although the transfer of cpDNAs is often considered a neutral change, the many examples of chloroplast capture may in fact represent the outcomes of positive selection in which new combinations of chloroplast and nuclear genes have a selective advantage. Although data for the mitochondrial genome (mtDNA) are much more limited than for cpDNA, it is possible that mtDNA is also transferred along with the cpDNA through hybridization and introgression. However, given the relatively slow rate of nucleotide substitution in the mtDNA (Palmer, 1992) and therefore the high genetic similarity between mtDNAs of related species, the transfer of mtDNA may not yield many new genetic combinations, in contrast to the possibilities with cpDNA.

Loss of Novelty Through Hybridization and Introgression

Hybridization may also retard genetic differentiation and lead to loss of genetic and biological diversity. For example, divergence between populations is a function of selection, drift, and gene flow, and the same is true at the interface of two species. Gene flow (i.e., hybridization) can retard or prevent diversification. Furthermore, genetic differences between species can be eroded by gene flow, or hybridization, between them, leading to a breakdown of species barriers and the potential loss of one species or the other.

The loss of the genetic integrity of a species often occurs when a rare species hybridizes with a more widespread relative, often with detrimental consequences for the rare endemic (Levin *et al.*, 1996). For example, human-mediated movement of species, such as introductions to islands, can pose a serious risk to the rare and endangered species of a given area. Hybridization with a more aggressive and more abundant relative may lead to swamping out of the genetic characteristics of the rare species, and possibly extinction. The Catalina Island mahogany (*Cercocarpus traskiae*) has been threatened by hybridization with *Cercocarpus betuloides* for many years, and conservation measures to limit hybridization and its aftermath are underway (Rieseberg, 1991). Similar situations exist for many rare species (Levin *et al.*, 1996).

Hybrid Swarms

Field botanists are more than familiar with the concept of hybrid swarms, which arise when interspecific hybrids are mostly or completely fertile. Following hybridization, fertile hybrids can self-fertilize or cross with other hybrids (and hybrid derivatives) or their parents. These mating opportunities provide a baffling array of genetic outcomes – even when only a single gene is considered. When the polygenic nature of most phenotypic traits is considered, the range of genotypes leading to any given phenotype is mind boggling and leads to the extensive phenotypic variation observed in the field when such hybrid swarms occur. Such swarms provide the ideal

conditions under which introgression can occur. Hybridization between species that can produce fertile offspring therefore leads to extensive genetic novelty on the one hand and perhaps loss of genetic uniqueness, through erosion of parental genotypes, on the other.

Hybrid Speciation

Homoploid hybrid speciation – that is, the origin of a new species via hybridization between two species without a change in chromosome number – is one of the most spectacular outcomes of hybridization (Rieseberg and Willis, 2007). This mode of speciation has been a staple of plant evolutionary biology for decades, but despite its conceptual framework, very few cases of homoploid hybrid speciation have been unequivocally demonstrated. The model of hybridization, followed by the sorting of a unique phenotype that moves into a novel habitat and therefore becomes isolated from its parents, is straightforward. However, the number of putative hybrid species greatly outnumbers those that have been analyzed in detail; and of those analyzed, very few provide convincing evidence of hybrid species formation (perhaps only 20 good examples; Gross and Rieseberg, 2005). Part of the problem is that, even with excellent genetic markers, it is difficult to determine (1) if a population or set of populations arose via hybridization between two (or more) other species and (2) if this set of populations should be recognized as a distinct species (Gallez and Gottlieb, 1982; see discussion in Soltis and Soltis, 2009).

Hybrid species are often expected to be “additive” of their parental traits, with this additivity manifested as intermediacy. However, numerous studies have shown that, for a single trait, hybrids may be intermediate, or they may resemble one parent or the other or exhibit a novel phenotype (McDade, 1990; Rieseberg, 1995). When the many traits of a plant are considered, hybrids are probably never true intermediates, but mosaics of traits that span the range of parental resemblance through intermediacy to novelty. The range of mosaic genotypes – and their expressed phenotypes – may make hybrid species highly polymorphic, with some genotypes at selective advantages and disadvantages.

The best-studied hybrid species in plants occur in *Iris* and sunflowers (*Helianthus*). Studies of the Louisiana *Iris* group (Riley, 1938; Anderson, 1949) served as the basis for the development of Anderson’s ideas on introgression. Three hybridizing species – *Iris fulva*, *Iris brevifolia*, and *Iris hexagona* – have contributed to the complex formation of *Iris nelsonii* (Arnold, 1993). This species complex has provided opportunities for studying the genetic architecture of interspecific traits and adaptation to different habitats.

Multiple and repeated examples of homoploid hybrid speciation have occurred in *Helianthus* (see Novel Genotypes Through Hybridization and Introgression; Heiser, 1949; Rieseberg *et al.*, 1995, 2006). The widespread cultivated sunflower, *H. annuus*, has hybridized with *Helianthus petiolaris* multiple times, and these hybridization events have yielded three hybrid species: *H. anomalus*, *Helianthus deserticola*, and *H. paradoxus*. Although these species share the same parental species, they reflect separate origins and different

combinations of parental genes. The consequence is that each hybrid species is unique, and each occupies a specialized, and environmentally extreme, habitat. *H. anomalus* occurs on sand dunes in the Southwest, *H. paradoxus* occurs in saline wetlands in Texas and New Mexico, and *H. deserticola* is found in the deserts of the Great Basin (Rieseberg *et al.*, 2007). Despite their divergence in ecological tolerances, these three derivative species have undergone concerted chromosomal rearrangements (Rieseberg *et al.*, 1995).

Hybridization and Polyploidy

Although hybridization at the homoploid level (see Hybrid Speciation), has significant consequences for plant evolution, hybridization manifests itself most strongly when combined with polyploidy. Both the number of species generated through polyploid origins and the extent of genetic and phenotypic novelty generated through polyploidy are greater than those for homoploid hybrids. Herein, both patterns and processes of polyploid evolution in plants are addressed, emphasizing the role that polyploidy has played in structuring plant genomes and how this complex genome structure results in genetic, phenotypic, and evolutionary novelty.

Types of Polyploids

Polyploids are typically classified as “autopolyploids” or “allopolyploids.” Although these terms themselves have a long and complicated history, today, autopolyploids are considered to have arisen from within a single species, and allopolyploids constitute those that arose via the combined processes of hybridization and chromosome doubling. Of course, nature does not follow these strict definitions, and polyploids tend to occupy a continuum from polyploidization within a single individual to interspecific hybridization and polyploidization; furthermore, some polyploids have only slightly differentiated chromosome sets, a situation Stebbins (1947, 1950) referred to as “segmental allopolyploids.” Despite these differences, most authors agree that most polyploids are derived from some form of hybridization – either between species or between individuals of the same (or different) population(s).

Ancient Polyploidy

Polyploids are very common among extant plants, with traditional estimates averaging approximately 50% (and some much higher) of all species of flowering plants being of polyploid origin (Stebbins, 1947, 1950, 1971; Grant, 1981; Goldblatt, 1980; Masterson, 1994). Polyploidy is also common in bryophytes and ferns. In fact, based on chromosome numbers, many of the most ancient lineages of land plants may be ancient polyploids. This hypothesis is based on chromosome numbers, and although it has been tested with genetic data, the arrival of genome sequencing promises a new and refreshing perspective on ancient polyploidy in plants.

The green plants are a clade of approximately half a million species with a fossil record of nearly 1 billion years. About 450 million years ago (Ma), the first plants emerged on land, and

their subsequent diversification was rapid and astounding. Today, the embryophytes (land plants) constitute liverworts, mosses, hornworts (these three collectively termed “bryophytes” although they do not form a clade), and a large clade of vascular plants (tracheophytes). The tracheophytes consist of the lycophytes (club mosses, spike mosses, and quillworts), the monilophytes (*Psilotum*, *Equisetum*, and ferns, among others), and the seed plants gymnosperms and angiosperms (flowering plants). The tracheophytes extend back in the fossil record to more than 400 Ma, with the angiosperms representing the most recently originating group, with the oldest fossils dating to approximately 130 Ma.

Ancient Polyploidy in Tracheophytes

Ongoing polyploid formation is common in tracheophytes, with polyploid species complexes (see Polyploid Complexes) of diploid and polyploid species in ferns and angiosperms in particular. An interesting observation of many ancient lineages of tracheophytes (e.g., lycophytes, *Psilotum*, *Equisetum*, and most homosporous ferns) is that they have very high chromosome numbers (on average, $n=57$). These high chromosome numbers led to the hypothesis that these groups were ancient polyploids whose diploid ancestors had gone extinct, given the antiquity of these groups (see Klekowski and Baker, 1966). Given the apparently high self-fertilization rates of these plants, Klekowski and Baker (1966) argued that the genetic polymorphism housed in the multiple chromosome sets of an ancient polyploid could offset the detrimental effects of selfing. This elegant hypothesis was favored until the use of genetic markers, developed in the 1960s for analysis of human genetics, made its way to studies of ferns.

The first studies of isozyme genetic markers in ferns clearly showed patterns of gene expression expected for a diploid individual, based on studies of diploid animals and flowering plants: one band for a homozygote and two for a heterozygote. If ferns were ancient polyploids, housing reserves of genetic variation because of their self-fertilizing breeding system, they should have complex genetics, with many isozyme bands, but this was not the case. However, ferns known to be more recent polyploids did have the complex banding expected of a polyploid. Given these results, Haufler and Soltis (1986) proposed that ferns with high chromosome numbers are not, in fact, ancient polyploids, but genetic diploids. These results could be interpreted in the following ways: (1) ferns were not now, and never had been, polyploid – their high chromosome numbers were achieved through some alternative mechanism, such as chromosome fission; or (2) ferns were, in fact, ancient polyploids but their genomes had been “diploidized” such that gene expression patterns were typical of diploids rather than polyploids.

These results for ferns triggered similar analyses in other ancient groups of plants with high chromosome numbers. Lycophytes classified in Lycopodiaceae (*Lycopodium*, *Huperzia*, and relatives; lowest numbers for each genus range from $n=22$ to 67) also have high chromosomes, as do *Psilotum* ($n=52$) and *Equisetum* ($n=108$). Application of isozyme genetic markers to all of these groups also revealed diploid gene expression despite high chromosome numbers (Soltis, 1986; DE Soltis and PS Soltis, 1988; PS Soltis and DE Soltis, 1988). Thus, if these plant groups are truly ancient polyploids,

they have lost their polyploid attributes and seem completely diploidized (“completely,” i.e., given the small number of genes examined). These plants await more sophisticated analyses, such as those now possible using genomic data. For example, a complete genome sequence has been obtained for a species of *Selaginella*, a spike moss, and no evidence exists for ancient polyploidy. Of course, *Selaginella* and its sister group, *Isoetes*, are among only a few groups of these ancient lineages that do not have the high chromosome numbers ($n=7$ and $n=10$, respectively) thought to be associated with ancient polyploidy. Genomic resources, or a complete genome sequence, for one of the other groups would be useful for addressing the question of whether or not these plants are ancient polyploids.

Ancient Polyploidy in Angiosperms

As in the tracheophytes generally, several lineages of angiosperms have consistently high chromosome numbers: Magnoliaceae (magnolia family), Myristicaceae (nutmeg family), Calycanthaceae (sweetshrub family), Lauraceae (laurel family), Salicaceae (willow family), to name a few. Most of these occur in the magnoliid clade, an ancient group that includes all of these families except Salicaceae. Stebbins (1950) hypothesized that these groups were all ancient polyploids, with additional, more recent polyploids present in several of these groups. In contrast to the data for lycophytes, *Psilotum*, *Equisetum*, and ferns application of isozyme genetic markers to these plant groups demonstrated complex banding patterns consistent with ancient polyploidy (Soltis and Soltis, 1990).

Unlike for tracheophytes, however, additional genomic resources have been developed for several of these putatively ancient polyploid angiosperms, and these allow for further investigation of ancient polyploidy. For example, the entire genome of *Populus* (in the willow family) has been sequenced, and this sequence reveals evidence of ancient tetraploidy (Tuskan *et al.*, 2006). Although not complete genome sequences, genomic resources for members of Magnoliaceae and Lauraceae also demonstrate ancient polyploidy (Cui *et al.*, 2006).

Interestingly, analyses of whole-genome sequences for several species of angiosperms with low chromosome numbers also show evidence of very ancient polyploidy. Even *Arabidopsis*, chosen as the first plant to have its genome sequence because its genome is very small, is actually an ancient polyploid, as are its relatives in the mustard family (Brassicaceae). In fact, a WGD can be traced, using genetic data, to the common ancestor of all angiosperms, with another WGD having occurred in the common ancestor of all seed plants (Jiao *et al.*, 2011).

These genome-based analyses for angiosperms demonstrate that all angiosperms are polyploid, but they have experienced extensive, and sometimes differential, levels of diploidization, followed by additional polyploidization, etc. It will be interesting to apply similar analyses to the older lineages of tracheophytes to see if they, too, harbor evidence of ancient polyploidy. Our expectation would be that this evidence would be even harder to find, given the older ages of these groups.

Polyploid Complexes

Polyploids and their diploid progenitors often form complexes of related and hybridizing species. A group of related diploid species may hybridize and form polyploid derivatives in a variety of combinations. These polyploids may backcross to various diploids, or they may hybridize among themselves and form additional high-level polyploids ($4x \times 2x = 6x$, $4x \times 4x = 8x$, etc.). These species may subdivide the habitat in such a way that new intermediate niches are occupied by the new species, which have been referred to as “fill-in taxa” (e.g., in *Antennaria* (pussytoes); Bayer *et al.*, 1991).

Complex patterns of hybridization and polyploid formation among a group of species may lead to the formation of a “compilospecies” – a group of interacting species that share a gene pool across ploidal levels. Although an interesting concept, few examples of compilospecies have been documented, although recent molecular data for the grass *Paspalum* (bahia grass) in South America are consistent with the compilospecies concept. Extensive gene flow among populations and between ploidal levels in a compilospecies can generate substantial genetic and phenotypic novelty that may confuse scientists but have significant ecological and evolutionary impact.

Polyploid species complexes may also generate asexual lineages that arise via the production of sterile hybrid offspring. Asexual diploid or odd-ploid lineages may perpetuate themselves via a combination of methods, such as vegetative reproduction and apomixis, the production of seeds without sexual reproduction. *Rubus*, which includes raspberries and blackberries, is notorious for forming asexual lineages associated with hybrids and polyploids. Anywhere from a dozen to hundreds of species of *Rubus* have been recognized based on morphological variants, most of which are either apomictic or otherwise asexual. Apomictic polyploid species complexes also tend to occur at high altitude and high latitude, in groups such as *Draba* (in the mustard family) and *Antennaria* (in the sunflower family).

Polyploidy and Diversification

Given the foregoing discussion, it should be obvious that hybridization and polyploidy generate extensive genetic and phenotypic novelty on which selection can act. Some groups seem to undergo unreduced gamete formation – the most common process by which genomes are duplicated – much more frequently than others (Ramsey and Schemske, 1998, 2002), and polyploidy is therefore unequally distributed across even the plant branch of the tree of life.

Analyses of the frequency of polyploids, in the context of their diploid relatives, have yielded estimates on the frequency of polyploid plant speciation. These estimates range from a low of 2–4% of angiosperm speciation events and 7% of fern speciation (Otto and Whitton, 2000) to 15% of angiosperm speciation events and 31% of fern speciation (Wood *et al.*, 2009) – values that yield standing estimates of polyploid frequency much closer to estimates based on chromosome numbers than do the estimates by Otto and Whitton (2000). These estimates, although highly speculative, relate to the

origin of polyploid species. However, rates of diversification must take both formation and extinction into account.

One way of examining diversification is by plotting species numbers across a phylogenetic tree – a depiction of the overall branching history of evolution. When investigating a causal factor for increased or decreased diversification (the net of speciation and extinction), species numbers are examined relative to the origin of a specific characteristic. For example, in an analysis of the possible causes of the early diversification of the angiosperms, Davies *et al.* (2004) tested such attributes as pollination syndrome, geographic distribution, dispersal mode, habit, and chromosome number, but none of them, at least alone, is significantly associated with diversification early in angiosperm history. However, although chromosome number was tested as a proxy for ploidy, ploidy itself was not investigated. Because of the dramatic changes that can occur to a genome after polyploidization, leading to a chromosome number that might no longer be recognized as polyploid, perhaps chromosome number itself is not an appropriate character; alternatively, ploidy might not have been significantly associated with diversification early in angiosperm history.

Plotting known genome duplication events on the phylogenetic tree for angiosperms suggests that, in fact, diversification at a deep level may be linked to increases in ploidy (Soltis *et al.*, 2009). A genome duplication event occurred before the origin of the large core eudicot clade (which contains ~70% of all angiosperm species), and additional duplications are associated with the origins of some of the largest families: grasses, legumes, and the potato/tomato family (Soltis and Soltis, 2009). Although more rigorous studies are needed, along with more information on the evolutionary history of WGDs, these analyses suggest that polyploidization events deep in the evolutionary history of angiosperms may have triggered rapid diversification.

In contrast to these results, Mayrose *et al.* (2011) reported that diversification rates among polyploids are lower than those among their diploid relatives, consistent with views by Stebbins, for example, that polyploid genomes provided buffering that retarded the rate of evolution and speciation. Although the results of Soltis and Soltis, 2009 and Mayrose *et al.* (2011) differ, this difference may actually be one of scale. Soltis and Soltis, 2009 examined diversification rates deep in the evolutionary tree, whereas Mayrose *et al.* (2011) focused on the tips. It is very possible that polyploidization events are like other types of mutations – most are lost as detrimental, but some persist as positive changes. Clearly, additional research is needed in this important area.

Recent Polyploidy

Hybridization and polyploidy may generate new biodiversity – often recognized as species – and they can have both positive and negative impacts on existing communities. Understanding the role that these processes play in generating and eroding biodiversity is crucial for establishing sound conservation practices. However, till date, data on hybridization and polyploidization are often anecdotal and not predictive. Furthermore, most polyploids have changed substantially since their

time of formation, making it difficult, if not impossible, to evaluate the contributions that are due to hybridization versus those due to polyploidization versus novelty that may have arisen within the polyploid species.

A handful of polyploid species have originated during the last 150 years. We know their time of origin because their parentage can be traced to human-mediated movement of plants, often transoceanically. Thanks to specimens housed in herbaria and other museum collections, it has been possible to pinpoint within a few years when certain polyploid species originated. The best studied of these polyploids are two tetraploids from the Pacific Northwest of USA. *Tragopogon mirus* and *Tragopogon miscellus* (in the sunflower family) formed in the early 1900s following the introduction of their parental species from Europe (Figure 1; Ownbey, 1950; Soltis *et al.*, 2004). These species have provided the opportunity to investigate what happens in a new polyploid species and whether or not there are any principles that may govern how polyploids evolve.

Duplicated genes have several possible fates: (1) both copies of the gene may be retained and both can continue to function as the original gene did; (2) one copy can be lost or silenced, leaving the second copy to carry out the original functions; (3) one copy can retain the original function and the second copy can take on new functions (called neo-functionalization); and (4) the two copies can subdivide the original functions so that each carries out a part of the original function, perhaps in a specific tissue or at a specific time, etc. When an entire genome is duplicated, as in a polyploid, all of

the genes are duplicated, and these options then occur for each gene. The resolution of these options makes for a very complicated set of possibilities, particularly when one estimates that a diploid plant has approximately 25,000–30,000 genes (about the same number as humans, mice, and fruit flies). Does each polyploid plant species resolve these options independently, or are there some rules that control which genes are retained in duplicate, which are lost, and which are neo- or subfunctionalized?

The question of what happens to duplicate genes in a new polyploid has been addressed in the two *Tragopogon* tetraploids. Surprisingly, in a series of studies (most recently Buggs *et al.*, 2012 and references therein), both species were found to lose copies of their genes much more frequently than they underwent gene silencing or neo- or subfunctionalization (most genes were retained in duplicate). Amazingly, more than 10% of the duplicate genes surveyed actually lost one member of the pair. Although this might be an expectation for an ancient polyploid that has undergone diploidization, it was not expected in recent polyploid that is only approximately 80 years old. Furthermore, certain types of genes – those encoding particular structural proteins – were more often retained than various types of regulatory genes, in contrast to theory on gene loss and to data for *Arabidopsis*.

The mechanisms for such genetic changes are unknown at this point, but abnormal pairing and breakage of chromosomes could lead to loss of duplicate genes. Interestingly, *Tragopogon* polyploids exhibit extensive chromosomal variation relative to their diploid parents and to all expectations of additivity for an allopolyploid, and this variability may result in the unusual genetic patterns observed (Chester *et al.*, 2012). The phenotypic manifestations of this genetic and chromosomal variation are unknown, but could be substantial (Figure 2).

Ecological Consequences of Hybridization

Hybridization and polyploidization generate novelty that may be manifested as ecological adaptations, such as the ability to occupy niches separate from those of the parental species. However, the ecological implications of hybridization on biodiversity extend beyond single plant species, or even plant communities. The diversity and structure of plants are used to define all ecological communities. But it is the biological diversity of organisms that live on plants – their herbivores, pathogens, pollinators, dispersers, root and leaf mutualists, and the natural enemies of these organisms – that contributes the most to total biological diversity. Interspecific hybridization of plants contributes to biological diversity in fundamental ways. Beyond generating biological diversity through introgression, speciation, polyploidization, and the processes described in the preceding sections, hybridization in plants increases overall biological diversity through its influence on the abundance and diversity of herbivores and their natural enemies, and their pathogens. In this section, the effects of plant hybrids on the biological diversity and community structure of higher trophic levels, herbivores, their natural enemies, and pathogens are considered. The conceptual model proposed in this section suggests that plant

Figure 1 Diagram showing the parentage of the two recent allotetraploids, *T. mirus* and *T. miscellus*, from their diploid parents, *Tragopogon dubius* and *Tragopogon porrifolius* and *T. dubius* and *Tragopogon pratensis*, respectively. The diploids are placed at the points of the triangle, and the synthetic (artificially produced) allopolyploids are on the lines between the parents, each near its maternal parent. The three naturally occurring allopolyploids are located inside the triangle. Reprinted with permission from Cold Spring Harbor Symposia on Quantitative Biology.

hybridization contributes to genetic diversity of plant populations, that genetic diversity increases biological diversity, and that biological diversity creates new opportunities for interaction diversity.

Genetic Basis of Hybrid Plant Resistance

The influence of hybrid plants on biological diversity depends on the resistance of hybrids to phytophages, that is, organisms that feed on plants. Resistance is the ability of a plant genotype to avoid attack or prevent the development of a specific herbivore or pathogen relative to other genotypes. Resistance is a genetic trait that determines the abundance of each species of phytophagous organism on a plant; consequently, the resistance of hybrid plants, relative to their parents, to phytophages contributes to the biodiversity, community structure, and interactions among phytophages.

The resistance of hybrid plants compared with parental species may be a polygenic trait, influenced by many genes, or a single gene, Mendelian trait; consequently, a number of genetic models have been proposed to describe and predict patterns of resistance. These models also vary in the type of

hybrids under consideration, as the genetic properties differ depending on whether the hybrid is a homoploid F_1 , an F_2 , backcross, or later-generation hybrid, or an allopolyploid. Patterns of susceptibility and resistance of hybrids to phytophages can therefore be complex. In some cases, genetic recombination may lead to higher susceptibility relative to the parents and hybrid breakdown, as coadapted gene complexes (perhaps composed of several resistance genes) from either or both parents are broken down. In other cases, the hybrid may combine the best of both parental species' defense mechanisms and be much more resistant; this outcome is particularly likely when hybridization is coupled with polyploidization, and the F_1 additive genotype is essentially stabilized. Furthermore, hybrids may be differentially resistant to generalist versus specialist herbivores. Finally, although the fundamental resistance or susceptibility of a plant to an herbivore or pathogen is genetically determined, the environment may also contribute to whether or not a certain genotype is attacked. The role of environmental variation in determining plant resistance is particularly important because some hybrid zones occur across steep environmental gradients, hybrids may occur at the range limits of each parent

species, and some hybrids are found in unique habitats where abiotic conditions differ. Plant stress, induced by environmental extremes, is known to make plants more susceptible to herbivores; thus, elevated levels of herbivory on hybrid plants in a given setting may be a direct result of stress rather than genetic composition (Whitham *et al.*, 1994; Fritz, 1999).

Communities on Plant Hybrids

Species richness of herbivores and pathogens on hybrids, in fact, varies, as predicted by the diversity of underlying genetic mechanisms of resistance, the type of hybrid, the environment, and the distribution of phytophages on the parental species (Figure 3). Species diversity will be greater on hybrids

than on either parent if the parent species have species-specific herbivores and hybrids are not completely resistant to them – hybrids will have herbivore communities derived from both parent species. The effects of hybridization on species richness will be small if the parental species share a large proportion of their herbivores, as is the case for hybrids between the willows *Salix sericea* and *Salix eriocephala*. Most of the gall formers, leaf miners, and leaf tiers occur on both plant species and hybrids. In contrast, several herbivores occur on one species and hybrids but not on the other parent. For example, *Pontania gracilis* occurs on *S. sericea* and hybrids and *Pontania pomum* occurs on *S. eriocephala* and hybrids. Likewise, the stem gallers *Rabdophaga rigidae* and *Rabdophaga salicisbrassicoides* occurs on *S. sericea*, but *Rabdophaga strobiloides* occurs on *S. eriocephala*. These herbivores are responsible for the higher diversity on hybrid willows compared with the two parents. Furthermore, a significant number of species occurring on hybrids may be unique in that they are not found on either parent species. On spruce hybrids in two locations in Michigan, 12.2% and 15% of herbivore species were unique to hybrids. About half of species are restricted to one or the other parent species, and 35% and 41.5% of herbivores on hybrids were found on both parent species. This result may reflect the underlying genetic novelty of the hybrids relative to their parents.

The combination of altered resistance of hybrid plants compared with parents, species-specific responses of herbivores to hybrid plants, and new combinations of coexisting phytophages on hybrid plants dictates that community shape (the relative representation of different species) will differ between hybrids and parent species and among genetic classes of hybrids. The ecological consequences of the novel communities of phytophages will depend on species abundances and how species interact with each other, and novel interactions (competition, mutualism, predation, and parasitism) are likely to result.

Species that have large effects on populations of other species in a community are called keystone species. Removing them from the community and measuring the responses of other species can reveal their indirect effects on community structure. Two such cases of indirect effects of keystone species on diversity and relative abundance of other species on hybrids were found for the gall aphid, *Pemphigus betae*, and the leaf beetle, *Chrysomela confluenta*, in the *Populus angustifolia*–*Populus fremontii* (cottonwood) hybrid zone (Whitham *et al.*, 1999). Removal of *P. betae* from hybrid trees reduced species richness by 32% and relative abundance by 55% of other herbivores in the system. The negative effects on diversity were due to elimination of the parasites and predators of the aphids and reduction of other herbivores, which benefit from aphid modification of the host plant. In contrast, removal of the beetle, which preferentially feeds on leaves of young plants, increased species richness of other herbivores by 120% and relative abundance by 75%. Defoliation by the beetle reduces the available foliage for several other herbivores, an intense competitive effect. Thus, when plant hybridization strongly alters resistance to even one herbivore, there may be a cascade of indirect effects on other species.

Parasitoids, predators, parasites, and pathogens of herbivores or plant pathogens typically outnumber herbivores by several fold, and therefore their diversity is an important part

Figure 3 Species richness in a *Eucalyptus amygdalina* – *Eucalyptus risdonii* hybrid zone (40 insect and fungal species). (a) Species richness in a *Eucalyptus obliqua*–*Eucalyptus baxteri* hybrid zone (25 insect and fungal species). Reproduced from Whitham TG, Morrow PA, and Potts BM (1994) Plant hybrid zones as centers of biodiversity: The herbivore community of two endemic Tasmanian eucalypts. *Oecologia* 97: 481–490. (b) Bars with different letters differ significantly at $p < .05$. Reproduced from Morrow PA, Whitham TG, Potts BM, Ladiges P, Ashton DH, and Williams JB (1994) Gall-forming insects concentrate on hybrid phenotypes of *Eucalyptus*. In: Price P, Mattson W, and Baranchikov Y (eds.) *The Ecology and Evolution of Gall-Forming Insects*, pp. 121–134. St. Paul: North Central Forest Experiment Station, Forest Service, USDA.

of the biological diversity supported by hybrid plants. Few studies have considered the effects of parasitoids or predators on herbivores occurring on hybrid and parental plants, but variation in abundance and fitness of herbivores on hybrid plants may be explained in part by the impact of this trophic level. Decreased levels of parasitism or predation could explain the higher abundance of some herbivores on hybrid plants compared with parental species. Higher parasitism of herbivores on hybrids may reduce the density and fitness impact of herbivores on hybrids. Parasitism by chalcid parasitoids did not differ among galls of *Andricus californicus* on *Quercus dumosa* and a wide range of hybrid genotypes. Mortality of aphids on hybrids of *Alnus incana* and *Alnus glutinosa* was intermediate between that of the two parents. However, parasitism rates of a seed-eating herbivore of two cattails (*Typha latifolia* and *Typha angustifolia*) and their F₁ hybrid were significantly greater on the hybrid, although densities of the seed predator were significantly lower on the hybrids. In this case, hybridization seems to directly affect herbivore susceptibility to parasites. Parasitism of the leaf miner *Phyllonorycter* sp. on oak hybrids was lower than on parental species, and lower parasitism of *Phyllonorycter salicifoliella* on willow hybrids was found in the field, but was not repeated the next year or on F₁ hybrid plants in a common garden experiment (Fritz *et al.*, 1999). Predation on beetle larvae on willow hybrids was intermediate between that on the parental species. There is a wide range of effects of parasitoids and predators on herbivores of hybrid and parental plant species. The outcome of these interactions is likely to influence the population dynamics of herbivores of hybrids and therefore their effects on hybrid plant fitness. One consequence of unique communities on hybrid plants is that related herbivores that share natural enemies may interact more intensely. Apparent competition, where differential parasitism causes negative density relationships between species, would seem to be more likely on hybrid plants. Coexistence of related species on hybrids might facilitate shifts in host utilization by parasitoids.

The interactions of plants with other species extend beyond herbivores and their natural enemies. Hybridization often results in novel plant architecture. F₁-type hybrids in the cottonwood hybrid zone between *P. fremontii* and *P. angustifolia* have greater numbers of lateral branches than parent species. Compared with parent species and backcrosses to *P. angustifolia*, these hybrids supported significantly greater numbers of bird nests. Northern orioles (*Icterus galbula*) and blackbilled magpies (*Pica pica*) were the most common species using hybrid cottonwoods as nest sites, but other common species using these trees were the American robin (*Turdus migratorius*) and the warbling vireo (*Vireo gilvus*) (Whitham *et al.*, 1999). Plants have mutualist or commensalistic interactions with endophytic fungi, which may have detrimental effects on insect and mammalian herbivores. In the *Quercus grisea* and *Quercus gambelii* hybrid zone, total endophyte frequency and frequency of *Gnomonia cerastis* was highest on *Q. gambelii* and was positively associated with hosts resembling *Q. gambelii*, but the frequency of *Coccochorella quercifolia* was most frequent on *Q. grisea* and on hybrids resembling *Q. grisea*. Although direct effects on the density of a leaf-mining moth (*Phyllonorycter* sp.) were not found, mortality of the tissue-feeding stage of *Phyllonorycter* sp. was positively associated

with the presence of *G. cerastis*. This study suggests the possible interaction between endophytes and an insect herbivore mediated by hybrid genotype. Mycorrhizal fungi are ubiquitous mutualists of plants that commonly facilitate nutrient uptake. How hybridization affects these mutualists is unknown, but the effects of high levels of herbivory that occur on some hybrid plants could be detrimental to mycorrhizae. Herbivory on pinyon pine, *Pinus edulis*, by a stem-boring moth reduced mycorrhizal levels by as much as 33%, but when moths were removed, mycorrhizae recovered. Thus, interactions between herbivory on hybrids and root mutualists may be antagonistic, resulting in more harmful effects on plant fitness. A rich diversity of ecological interactions (interaction diversity) is likely to occur on hybrid plants. Some interactions on hybrids will vary on themes present on parental species; other interactions will be unique due to unique species combinations on hybrids (e.g., mutualists and competitors). Still other interactions will be unique because novel or transgressive (traits that lie outside the parental range) traits of the hybrids themselves (e.g., morphology, phenology, or chemistry) create novel conditions for evolution among herbivores, pathogens, and their natural enemies.

Conclusions

The last few years have witnessed a resurgence of interest in hybridization and polyploidy, perhaps prompted by the ability to ask both old and new questions with genomic data. Ancient polyploidy seems rampant across plant lineages (except possibly for gymnosperms, but see Burleigh *et al.* (2012)). The question is no longer: is species *x* diploid or polyploid, but how many rounds of genome duplication are represented in the genome of species *x*? Given multiple polyploid genomes, how do the many duplicate genes interact to generate genetic and phenotypic novelty? Do consistent patterns emerge, suggesting that a set of principles may control the evolution of polyploid genomes? Are plants burdened by too many genomes and too much DNA (the genetic obesity hypothesis), and what are the mechanisms and pace of diploidization?

The questions raised here are specifically aimed at solving aspects of plant genetics and evolution, but ancient and recent polyploidy characterizes all lineages of eukaryotes, including vertebrates. Although polyploidy is much more common in plants, strong evidence supports multiple rounds of ancient WGD in the ancestry of vertebrates. Therefore, whatever we learn from polyploid plants may be useful for understanding the processes governing our own genomes, and those of many animals and fungi.

Finally, hybridization and polyploidization are sources of genetic (and phenotypic) novelty that may have long-term ecological and evolutionary consequences. Hybridization – including hybrid swarms, introgressants, and allopolyploids – may confer novel conditions that affect not only plant biodiversity but also the diversity of many communities that rely on plant communities. As drivers and shapers of biodiversity, these processes are fundamental for understanding the roles of plants on Earth.

Indigenous Strategies Used to Domesticate Plants in Brazilian Amazon

Giorgini A Venturieri, Universidade Federal de Santa Catarina, Florianópolis, Brazil

© 2013 Elsevier Inc. All rights reserved.

Glossary

Barreais Soils naturally enriched with organic matter and clay carried by the rain and/or a river.

Caboclos Cultural and/or racial crossing between European and indigenous populations.

Macaxeiras Group of varieties of manioc (*Manihot esculenta* Crantz) with low levels of cyanidric acid. These varieties may be consumed without prior treatment to lower their toxicity, as must be done with other varieties of wild manioc. Synonyms: Sweet manioc and aipim.

Marimba Elevated flooring made of wood, used in flooded areas for placing cattle or plants during river flood periods.

Reproductive isolation When a derived population is not able, for some reason, to breed and obtain fertile progeny with the original population.

Wild manioc Manioc with a high level of cyanidric acid.

In this article, concepts are discussed relating to natural biodiversity used to form new crops and for the improvement of already domesticated species. A majority of examples come from the underexploited plants used by Amazonian indigenous people, little known in the international scientific literature, but which are splendid examples of the capacity for breeding and selection of traditional communities. The article also gives curious reports of Amazonian Indian practices of management and interchange of germplasm from useful plants.

What is Domestication?

The evolution of a plant occurs when there is a selection; this can be the result of human activity, which generally values attributes of interest to people in detriment to those necessary for the plant's own survival in the wild. When this process reaches high levels of genetic modification, to the point that human aid is necessary for survival, the plant is considered to have achieved the stage of being domesticated (Harlan, 1975). Useful plants occur at various stages of domestication that require different degrees of management and cultivation. Generally, the more domesticated the plant, the more demanding it is as to the degree of management and cultivation, but the fact of a plant being managed or cultivated does not imply that it is domesticated. However, any plant that has been managed or cultivated for a long time is inevitably undergoing modification towards domestication because it is placed in environmental conditions improved by humans, who reduce or eliminate the usual processes of natural selection such as competition and predation. Domestication is related to the plant's genetic response, management, and cultivation and human activity in dealing with the plant (Harlan, 1975).

This article will deal principally with practices still used by Indians and Caboclos (rural peoples often of mixed ancestry) of Amazonia who may directly (conscious selection) and indirectly (unconscious selection) be inducing modifications in natural plants in the direction of their domestication.

How Does Domestication Happen?

The forces of selection, resulting from management practices or from cultivation *per se* and as induced by farmers, may be consciously or unconsciously provoked (Harlan, 1975). In conscious selection, the farmer sees some interesting attribute in a plant and seeks to propagate it in some way, be it by sexual means (seeds) or asexually (generally by trying to induce a portion of stem to take root), thus forming a new population. If the characteristic selected has good inheritability – that is, it can be transferred from one generation to another – the result is an improved population. In unconscious selection, as the name indicates, this selection does not occur but the populations are modified due to some human intervention, generally in the environment or harvest system, which ends up benefiting some segment of a population to the detriment of the others, generating a selected population. The classic example of unconscious selection is that of rice, which upon being harvested has seeds in its panicle that do not easily fall from the plant. When these seeds are planted, they carry alleles that favor this characteristic, which is selected increasingly more favorably with each harvest. Seeds of domesticated rice today do not fall as easily from the panicle as do those of more primitive varieties (Harlan *et al.*, 1973).

The well-known “genetic drift” of the classic works on evolution is also very much associated with the process of domestication. Genetic drift occurs when a very small portion of a certain population is taken to another area that is isolated and it regenerates there, but does so only with the descendants of the few individuals introduced therein (Figure 1). Many times this process does not bring gains in productivity but does induce an increase in more or less stable varieties that end up forming the “local varieties.” This process is very common among farmers who have the habit of collecting only a few seeds from a given plant for planting on their farms or villages, generally far from the original population and isolated by some environmental barrier. This may be a large river or, in the case of plants typical of disturbed environments such as the plants domesticated in farm plots, a climax forest in which such species do not occur.

Figure 1 Hypothetical representation of genetic drift for the grain color character, considered not to have adaptive value. Genetic drift occurs when the sample is small and does not represent all the classes of a determined characteristic.

Currently domesticated plants were some time ago wild plants which were in stages used, then managed, and finally cultivated (Clement, 1992a, 1992b). The process of domestication, for the majority of species, took thousands of years. For corn, whose domestication process is the best known, it is estimated that the process took more than 3000 years (Iltis, 1986). If, for an annual plant, so much time was spent, one can imagine how long it took to domesticate the Amazonian fruit trees that are perennials. The appearance of a domesticated plant may also be sudden, due to some mutation that provokes a very radical modification in the plant, such as alterations in the number of chromosomes. For example, Cupuaçu (*Theobroma grandiflorum* Schum) is an Amazonian fruit highly valued for its pulp, but whose seeds constitute 32% of its total weight. A triploid variety that produces only pulp and no seeds has been found and is being propagated by grafting (Venturieri and Mendonça, 1985). Another case of chromosome number modification is observed in Guaraná (*Paullinia cupana* Kunth var. *Sorbilis* (Mart.) Ducke), a stimulant plant due to its high caffeine content, initially of restricted use by Amazon people, has now spread across the world thanks to the energizer and soft drinks industry. The variety *Sorbilis*, domesticated by the Sateré Maué, where it originated, has 210 chromosomes, while other species of the genus have 24 (Freitas *et al.*, 2007). This recent polyploidization is an apparently recent event because the natural genetic variability of domesticated guaraná, assessed by molecular markers, is small (Atroch *et al.*, 2009). Peach palm (*Bactris gasipaes*

H.B.K.), considered to be the only palm tree domesticated in the Americas, is probably a hybrid between *B. dahlgreniana* Glassman and *Guilielma insignis* (Clement, 1988). Finally, there is the suppression of some gene or group of genes that made a species poisonous, as is the case with wild manioc, with a high level of cyanidric acid, producing macaxeira with very low levels of cyanidric acid. Nowadays, with the help of advanced selection and biotechnology techniques, the process of domestication can be considerably shortened, but still 99% or more of the species currently domesticated were achieved by farmers before the “green revolution” (Harlan, 1975).

The greater the diversity of these plants, in terms of species as well as of varieties within each of these species, the greater would be the options of choices for humans.

For selection to be efficient there must be reproductive isolation between the population selected and the original group from which it was taken. If there is no isolation, the new population again crosses with the original population and becomes similar to it, without achieving any gain. The more efficient this isolation, the more rapidly a given population may be domesticated (Figure 2). In indigenous peoples' systems, this isolation is achieved by environmental barriers or management practices. In summary, to obtain a domesticated plant there must be (1) the chance for choice (genetic diversity), (2) discovery of useful plants and obtainment of interesting varieties, and (3) reproductive isolation of the varieties selected so that they do not return to the wild state. How were these predicates achieved for Amazonian plants?

Figure 2 Diagram exemplifying the effect of reproductive isolation. A selected sample with large fruits is removed from an original population. (a) When the isolation is efficient – that is, when the new population is planted in a plot at a distance that avoids gene exchange with the original population – the new population will produce descendants with large fruits. (b) When isolation is not efficient, the new population may cross with individuals from the gene group that gave rise to it and re-establish the characteristics of the original population among its descendants. The more effective the reproductive isolation, the more rapidly genetic gains are achieved.

The Chance for Choice (Genetic Diversity)

The Amazonian forest offers a grandiose biodiversity with an immense number of useful plants for domestication. Considering only the fruiting species (Benza, 1980; Cavalcante, 1991; Clement, 1999; Correa, 1926–1969; Hoehne, 1946; Kerr and Clement, 1980; Kerr and Posey, 1984; Le Coint, 1947; Smith *et al.*, 1992), one may prepare a list with more than 250 typically Amazonian species, some of which are internationally recognized, others with use restricted to Indians who extract them from the native forest, and other “little-known” species in general use among the civilized

population that have undergone Indian influence. Certainly, if one considers the vastness of Amazonia with its 4 million km² and its incredible variability of plant species, estimated to be between 50,000 and 60,000 for the higher plants alone (Clement *et al.*, 1982), and the current state of economic botany in the region, it may be concluded that this list may still be increased considerably. For example, in two expeditions specifically planned for collecting potential fruiting species in the Amazon region, 10 species were attained that had not yet been cataloged (Instituto Nacional de Pesquisas da Amazônia/Núcleo do Acre, 1984; Venturieri *et al.*, 1986/1987).

The Discovery of Useful Plants and Acquisition of Interesting Varieties

In the eyes of “civilized” society, it is difficult to understand the process of discovering uses for plants. The Indians experiment with almost everything new that they find in the forest or that is brought to them by white people. As presents, they like receiving new plant species and varieties, such as the exotic plants that have recently been introduced in their cultures. The Kayapó Indians are very fond of mango, an Asian tree, and plant the seeds everywhere (Kerr and Posey, 1984), as do the Nambiquara Indians. Some Indians describe methodologies for discovering the usefulness of plants by employing concepts that are difficult to understand; for example, an Indian explained to me that the discovery of papo-de-peru plant (*Aristolochia* sp.) served as an antidote to snake venom because of the fact that “its flower looked like the skin of a snake.” It is common for them to risk their lives for discovery. Among the Hahaintesu group of the Nambiquara the ingestion of the aril of seeds of a *Philodendrum* sp. (Figure 3), the latex and fruit of which they recognized as very poisonous and capable of causing death was witnessed. They would split the fruit and with tweezers carefully remove the seeds so that they were not contaminated by the latex and then place them in their mouths to suck the arils, doing so carefully so as not to bite the seeds, which were later discarded. These Indians eat tarantulas (Setz, 1991) after singeing them to remove hairs that can cause irritations to the skin (in this case, in the mouth). They also cook and eat the tuberous stalk of a plant of the genus *Zamia*, which if eaten raw causes a strong headache (Figure 4). Apparently, the process of discovering a plant’s usefulness is by trial and error since the analogies between aspect and use are not logical. From the amount of information existing on edible and medicinal plants, one may imagine how many lives were lost and pains felt by these intrepid researchers.

Domesticated plants are generally described as having “appeared” through some myth. Among the Hahaintesu group of the Nambiquara there is a myth that describes the origin of man, whose head was the gourd (*Crescentia cujete* L.), whose teeth were the corn (*Zea mays* L.), whose ear was the lima bean

Figure 3 *Philodendrum* sp., a poisonous species whose seeds are removed from the fruit with the aid of tweezers and the aril is sucked carefully so as not to bruise the seeds, which are also toxic.

(*Phaseolus lunatus* L.), whose bones were the manioc (*Manihot esculenta* Crantz), and whose scrotum was the cará yam (*Dioscorea trifida* L.) (Figure 5). In the Kayapó myth, corn was acquired from the stomach of a rat that lived in an enormous tree in the middle of an area that was being prepared for planting; the strength of the entire tribe was needed to fell the tree (Lukesch, 1976). Another Kayapó myth mentions that sweet potato, macaxeira, and banana were brought by the “daughter of the rain” who came down from the sky, became an ordinary Indian, married, had children, and during a time of hunger returned to the sky and brought back these species that were then cultured so that the tribe never again went hungry (Lukesch, 1976). Others describe useful plants as being inherited from conquered people. The Tikuna recognize that many of the obviously domesticated fruits were already present when they arrived, possibly derived from the Omagua Indians, whom they expelled (Ailton Krenak, União das Nações Indígenas, personal communication), or they negotiated with other tribes (among the Hahaintesu group of the Nambiquara there is a variety of manioc called the “manioc of the Wassuso,” a tribe from the same linguistic group that became practically extinct – in 1985, there was only one elderly woman of this tribe).

Figure 4 Indian boy of the Hahaintesu group of the Nambiquara showing a plant of the genus *Zamia*, whose tuberous stalk can only be eaten cooked. When ingested raw, it causes a strong headache.

Figure 5 Species from the Nambiquara myth about the appearance of cultivated plants cultivadas: (a) The head is represented by the calabash (*Crescentia cujete* L.), (b) the teeth by corn (*Zea mays* L.), (c) the ear by the lima bean (*Phaseolus lunatus* L.), (d) the bones by manioc (*Manihot esculenta* Crantz), and (e) the scrotum by the cará yam (*Dioscorea trifida* L.).

The Indians' diet is based on many plants and their varieties. One commonly finds up to 40 varieties of manioc per indigenous tribe (Kerr and Clement, 1980; Boster, 1984; Elias *et al.*, 2000), witnessing the dynamism these people have for renewing these varieties. Manioc is usually propagated by stakes (cloned) which avoids combination between genotypes. However, if this were always the case, how would recruitment of new varieties for selection exist? How would one justify the great number of varieties observed among the Indians? Contrary to what is found in the literature of modern

agriculture, manioc is also propagated by seeds (Kerr and Posey, 1984; Pujol *et al.*, 2002). Plantules derived from seeds make possible new combinations resulting from crossing preselected parents propagated by stakes. A curiosity, volunteer seedlings of cassava emerge from a bank of dormant seeds in the soil established during the previous cycle(s) of swidden cultivation, 3–30 years/cycle (average approximately 10 years) (Elias and McKey, 2000). Dormant seeds need high temperature to germinate and remain ungerminated on lower temperature proportioned by shade through the fallow period;

they germinate synchronously after vegetation is slashed and burned. At the time of harvest, they decide whether to include the plants among those that will be vegetatively propagated and so incorporate the seedling as a new cultivar. As a consequence, the cassava germination process has a short relation with swidden cultivation and so, with its domestication (Elias and McKey, 2000; Pujol *et al.*, 2002). The Indians of the upper Rio Negro recognize plantules of manioc as derived from seed banks of old plantings in areas that have regenerated and been slashed and burned anew. This recognition is easy because the plantules derived from seeds display their cotyledons (Paulo Sodero Martins, Escola Superior de Agricultura “Luiz de Queirós,” personal communication). Traditional farmers from Ubatuba – SP, southern Brazil, also recognize cassava seedlings by their pivotal roots, contrasting cuttings that have lateral roots (Sambatti *et al.*, 2000).

The Hahaintesu group of the Nambiquara in 1985 possessed only nine varieties of macaxeira, almost all recently introduced after their areas were demarcated and their extermination by whites was interrupted. The increase in varieties is an indication that peace may be giving the Indians a chance to recompose their genetic collection of plants (Boster,

1984). Generally, as in the case of birth control, the administration of genetic resources is directed by women (Kerr and Posey, 1984). In the case of the Hahaintesu group of the Nambiquara, an elderly Indian woman (as mentioned earlier, the last of the Wassuso, married to the Indian Papai) possessed a great knowledge and love for agricultural plants, and others frequently brought her new plants and varieties. This woman would plant them in different environments and evaluate them. Those that were approved she handed over to the rest of the tribe for planting. This Indian woman and her garden fulfilled what would be the role of “curatorship and experimental station for genetic resources” in our society.

The Amazonian Indians highly value esthetics, as expressed through their clothing, body decorations, and basketry, which are generally exuberant in both form and color. This sentiment is also reflected in the plants and varieties domesticated by them. Examples include peach palm (*Bactris gasipaes* Kunth) (Figure 6(a)) and peppers of the genus *Capsicum* (Figure 6(c)) and cubiu (*Solanum sessiliflorum* Dunal.) (Figure 6(e)), which have a large variety of colors, sizes, and shapes. Among Indians, selection is also made by productivity and taste. Peach palm, one of the best-domesticated plants of the humid

Figure 6 Good examples of the great variety of colors, sizes, and shapes of domesticated plants selected by Amazonian Indians: (a) Peach palm (*Bactris gasipaes* Kunth), (b) Biribá (*Rollinia mucosa* Baill.) var. Tikuna, (c) peppers of the genus *Capsicum*, (d) abiu (*Pouteria caimito* Radl.) var. Tikuna, and (e) cubiu (*Solanum sessiliflorum* Dunal). See also color insert (this volume). (b, d) Reproduced with permission of Clement CR.

tropics, can produce up to 50 t ha⁻¹, with varieties selected for flour or oil and others that easily release the skin and have a refined flavor for cooking; there are also varieties with and without spiny trunks (Clement, 1988; Clement and Mora Urpi, 1987). In the state of Roraima, a Brazilian state in southwestern Amazonia, 78 morphotypes of *Capsicum* peppers have been identified (Barbosa *et al.*, 2002). Cubiu (*S. sessiliflorum* Dunal.), a fruiting plant similar to tomato, produces up to 100 t ha⁻¹ and has varieties with eight different shapes ranging from fusiform to semirounded, with colors ranging from yellow to purple (Silva-Filho *et al.*, 1993, 1999).

New varieties are also achieved through barter, raiding, and dower. Groups of friendly Indians visiting from other tribes take varieties as presents. Rival Nambiquara trade varieties in a ritual that is difficult to understand. They peep at each other from opposite sides of a river, without exposing themselves so as not to be killed; they sing and call out challenges. Suddenly, they gain confidence and cross the river to leave presents that sometimes are repaid. After the exchanges they go back to being mortal enemies. Among the Alantesu group of the Nambiquara, after marriage is consented to for a woman, some compensation is required from the groom, which may take the form of labor, a bicycle, a radio, or some other article or group of articles. When the debt is paid, the husband takes his wife and with her some plants, which introgresses genotypes from other tribes. Kidnapping is very common among the indigenous tribes of Amazonia (Black *et al.*, 1991). They kidnap children (the chief of the Ureu-au-au Indians, shown in a 1970s documentary about colonization in Amazonia along the BR-364 highway in the state of Rondônia, was a white man without any cultural traces of white civilization). Women are kidnapped, which seems to be a common practice among the Indians that does not annoy the kidnap victim for very long. Among the Hahaintesu group of the Nambiquara, a kidnapped woman was seen, who was imprisoned in a straw hut from which escape would have been easy and was guarded by her kidnapper, who stayed nearby. During the first days, she was aggressive toward those who approached her; two days later, she was seen laughing among the other Indian women. It was later learnt that she returned to the agricultural plots of her original tribe and brought back new varieties of manioc, and thus increased her standing with her new tribe.

Domesticated plants return to their wild state if the selective human pressure is relaxed (Harlan, 1975); therefore, there is a close relation between humans and domesticated plants. This relation is so intimate that gene introgression observed in Indian populations in Amazonia (Black *et al.*, 1991) may be associated with the introgression also found among populations of domesticated plants, such as is observed in peach palm (*B. gasipaes* Kunth) (Picanço *et al.*, 1999) and in caiaué (*Elaeis oleifera* Cortés) (*E. Barcelos*, Embrapa Amazonia Ocidental/Manaus, personal communication, and data partially published in Barcelos *et al.*, 1999).

Among the Tikuna in the region near Leticia, Colombia, there is a tribal custom that reinforces plant selection: "All fruit or other edible product that is especially large or flavorful is divided among the tribe and seed planted." This process, practiced over many generations, led, by massal selection, to an increase in desirable alleles, giving rise to the domestication

of fruiting species such as peach palm (*B. gasipaes* Kunth; Figure 6(a)), biribá (*Rollinia mucosa* Baill.; Figure 6(b)), and abiu (*Pouteria caimito* Radl.; Figure 6(d)) (Kerr and Clement, 1980). The fruiting species of that region have very beautiful varieties with giant fruits, showing clear signs of being domesticated; therefore, this is suggested as a center of domestication (Clement, 1989).

The Selection, Fixation, and Status of Amazonian Plant Domestication

Reproductive Isolation

For one population to be different from another, it must fragment off from the original and in some manner maintain itself distinct in genetic terms; in other words, it should have very low or nonexistent chances of crossing with individuals of the population from which it originated. Any reproductive barrier is capable of permitting the fragmentation of a population and its differentiation into subpopulations. Many isolation mechanisms are known from cultivated plants: Geographic and ecological separation, differences in time of blooming, self-fertilization, translocation races, polyploid races, gametophytic factors, cryptic chromosomal differences, and meiotic irregularities (Harlan, 1975). These mechanisms may occur simultaneously and be imperfect, and if the subpopulations meet someday some degree of hybridization may occur. Subpopulations with potential for intercrossing are called varieties. When the isolation is perfect and there are no longer possibilities for a natural cross to occur, then with the generation of fertile progenies a new species has been formed.

The Environment

Practices capable of inducing modifications in the structure of a population are intimately related to the physiognomy of the site and to the ecological restrictions that each environment offers. In Amazonia, although there are a range of ecosystems (for climate, see Salati, 1985; for soils, see Jordan, 1985; and for vegetation, see Pires and Prance, 1985) and a varied number of singular strategies used by the Indians who practice agriculture on lands with very low trophic support – such as the use of barreais near the rivers (Hill and Moran, 1983), in the savannas, with the formation of "managed islands" or apêtê of the Kayapó (Anderson and Posey, 1989), and plaza towns with ditches and roads called "garden cities" managed by the Kuikuro Indians (Heckenberger *et al.*, 2008). Recently, earthworks related to water management for irrigation, drainage, and fishponds were discovered in the Amazon, all sophisticated systems of agriculture, constructed before the conquistadors arrived. They are: The raised fields on flooded areas at the Marajó Island in the Amazon delta (Rossetti *et al.*, 2009; Roosevelt, 1991; Schaaf, 2008), Coastal Amazon of French Guiana (Rostain, 2010), and Baures region and the larger Llanos de Mojos in the Bolivian Amazon (Erickson, 2010), and ring ditches, also referred to as "geoglyphs," along the Branco, Mamoré, Madeira, Orton, Madre de Dios, Beni, and Guaporé rivers in the Brazilian and Bolivian Amazon (Erickson, 2010; Pärssinen *et al.*, 2009; Saunaluoma, 2010;

Schaan *et al.*, 2008). The oldest earthworks dated back to AD 300, the majority were from between AD 400 and 1400, and the last known to be constructed was from around AD 1700, almost all were abandoned around 1500 (Erickson, 2010; Pärssinen *et al.*, 2009; Roosevelt, 1991; Rostain, 2010; Saunaluoma, 2010; Schaan, 2008). Sophisticated systems of agriculture require genetic material of high productivity, and possibly the people who manned the earthworks generated collection of useful plants and cultivars that we are unlikely to discover how they were achieved. The abandonment of such costly construction as the earthworks was certainly linked to population declines, and with them went many cultivars because they need human intervention to maintain their genetic status (Harlan, 1975). It is speculated that they were adopted by indigenous groups remaining, and much of this material can still be found and collected (Lima *et al.*, 1997). Currently agriculture in indigenous communities is basically practiced on (1) upland areas (terra firme) covered by forests and (2) the river floodplains (várzeas). On terra firme covered by forest, agriculture is practiced in cycles of felling, burning, planting, and fallowing, also called slash-and-burn or swidden fallows. This is the most applied system of agriculture in Amazonia. A site with exuberant forest is located and the understory trees are cut first, followed by the large ones. Three months later, fire is applied. The ashes and organic matter formed by decomposing tree trunks nourish the soil for at most 4 years. When these soils are exhausted, cultivation of annual plants is abandoned and a new cycle must begin. Among Indians and many caboclo communities, this is not a complete abandonment because there is a subsequent recuperation stage of planting with useful perennial plants (Denevan *et al.*, 1984). This system of apparently migratory agriculture has been very efficient in improving plants because each plot receives some seeds of selected plants. Because the plots are relatively isolated from each other, as if islands within the forests, and the majority of plants cultivated in them do not occur inside the forest, the latter serves as a barrier to gene flow (Clement, 1987) (Figure 1). On terra firme, the soils are generally poor and need fertilizing, generally with the ashes resulting from the felling and burning of the original forest that covered them. On terra firme there are also areas that are cultivated continuously, although they are rare. These are the *terra-preta-do-índio* (Indian black earth, also called Amazonian dark earth), anthropomorphic soils that are very fertile due to having been enriched by organic detritus and charcoal deposited over countless generations by the Indians who inhabited them (Steiner *et al.*, 2007) (Figure 7). They usually have 2–5 ha, but 100 ha or more can be found, and owing to their fertility are preferred even today by white people for planting (Hiraoka *et al.*, 2003; Lehmann *et al.*, 2003; Smith, 1980; Steiner *et al.*, 2007).

Agriculture on periodically flooded lands is practiced on high and low várzeas and on river banks in cycles dictated by seasons of high and low water. Despite this inconvenience, these lands are highly fertile and demand little labor for clearing and planting. On the high várzeas, where flooding rarely occurs, perennial plants that can survive some time with roots submerged and annual plants are cultivated. With some risk, perennial plants typical of terra firme are also cultivated on high várzeas (Smith, 1996).

Figure 7 Anthropogenic soil of the “Indian black earth” (*terra-preta-do-índio*). Its great fertility is caused by the accumulation of charcoal, ashes, wastes, and excrement of domestic animals. Many perennial and annual plants are cultivated on these soils. Andirá river, Barreirinha, AM, Brazil.

These two groups of ecosystems have caused a great division between groups of species and varieties of domesticated plants. For the plants most domesticated among Indians, such as manioc (*M. esculenta* Crantz), corn (*Z. mays* L.), and lima bean (*P. lunatus* L.), short-cycle varieties were developed capable of being cultivated on the várzeas before the floods. Although plantain banana (*M. x paradisiaca* L.) is an exotic and perennial species, the variety known as *pacovi* (Cavalcante, 1991), with small bunches and an extremely short productive cycle, are cultivated. The Indians also developed cultivation systems for it that are adapted to the várzea. For plants propagated by stakes, such as manioc (*M. esculenta* Crantz), when floods arrive the young plants are removed from the soil and placed in a canoe or higher site for planting when the waters recede. In the case of banana plants, marombas (wooden structures elevated above the water level) are made in which the young plants are placed with a little soil and fertilizer so that they are sufficiently grown to be planted when the waters recede. Recent discoveries have provided information about how the floodplain of the Beni river in Bolivia was cultivated by the ancient Indians. They elevated fields of up to 2 m high, known as camellones that are constructed to be above the height of floodwaters, and are surrounded by water channels. The elevated fields are somewhat like the raised beds that some vegetable gardeners construct, though on a much larger scale (from 0.7 up to 176.4 ha). During the rainy season, the surrounding channels fill with floodwater, preventing the crops in the fields being washed away. The water can then be used to irrigate and provide nutrients to the camellones during periods of drought (Erickson, 2010). There is also a similar system used by the ancient Marajoara Indians, who cultivate the “tesos” of Marajó Island, which are elevated fluvial landforms upon which to build their settlements and ceremonial centers of their communities and that eventually increased their height and size (Rossetti *et al.*, 2009) using soil from artificial lakes carved next to serve as fishponds and water reservoirs (Schaan, 2008). On those hillocks Indians could escape from the annual flood. Tesos and campos inundáveis do Marajó are considerably less fertile than várzeas close

to the Andes, the Solimões/Amazon Rivers and their tributaries of white water, and, even today, in contrast to floodplains, closer to the Andes, and it is very hard to grow corn there. Nevertheless, manioc produces well and fruits are profuse. Even today manioc flour is the mainstay in the diet of rural peoples and those living in urban centers consume fruits of palms (mainly açaí and bacaba) and fishes. Many fruits can be collected on the tesos – muruci (*Byrsonima crassifolia* Rich.), mangaba (*Hancornia speciosa* Gomes), bacaba (*Oenocarpus bacaba* Mart.), tucuman or tucum (*Astrocaryum vulgare* Mart.), inajá or najá or anajá (*Attalea maripa* Drude), caju (*Anacardium occidentale* L.), bacuri (*Platonia insignis* Mart.), araçá (*Psidium guianensis* Swartz), muçajá (*Acrocomia aculeata* Lodd), and in the lowlands açaí (*Euterpe oleracea* Mart.), miriti (*Mauritia flexuosa* L.), and taperebá (*Spondias mombin* L.) – so, apparently the Marajo Island mound habitants had a diet similar to what caboclos have today. Várzeas are reputed to have higher potential to produce food than terra firme, and were capable of having maintained a quite dense population, as reported by sixteenth-century chronicles. It is estimated that at the time of discovery, on terra firme there were 0.2 inhabitants km⁻² and on the várzea 14.6 (Denevan, 1976) – numbers that are higher than those currently observed in Amazonia. Population estimates for the evaluated wetlands are certainly not as high if one takes into account that the foraging areas used by the Indians, in the dry season, were bigger. A clue to how extensive these foraging areas were may be given by the Tupi names of some towns of the Amazon basin beginning with a plant name followed by the suffix “tuba,” “duba,” “teua,” “deua,” “tida” and “diva” which means “a land of” or “with a profusion of” (Masucci, 1979; Barbosa, 1955), such as Inajatuba (an allusion to inajá *Attalea maripa* (C. Serra) Drude); Tucumduba, Tucumandeu and Tucumdiva all in allusion to tucum (*Astrocaryum vulgare* Mart.); Marituba an allusion to mari (*Poraqueiba paraensis* Ducke ou *P. sericea* Tul.); Muçajatuba an allusion to muçajá (*Acrocomia aculeata* Lodd); Miritituba and Mirititeua allusion to miriti (*Mauritia flexuosa* L.), Timboteua (an allusion to timbó (*Lonchocarpus utilis* Smith), Jabatiteua (possible a corruption of abati, that means maize, *Zea mays* L.); Ananindeua (an allusion to anani = ananin, *Symphonia globulifera* L.); Caranandeu (an allusion to caranã (*Mauritia carana* Wallace), Açaiteua and Açaitiva an allusion to açaí (*Euterpe oleracea* Mart.); Ajuruteua (in allusion to ajuru (*Chrysobalanus icaco* L., Caratateua in allusion to cará (*Dioscorea trifida* L.), Jutaitiva (in allusion to *Hymenaea courbaril* L.), Arapartiva (in allusion to *Macrolobium acaciaefolium* Benth).

The Management System

The management system causes environmental changes that can influence the demography and genetic structure of a population. For there to be selection and consequent domestication, there must be differentiated reproduction and survival for the genotypes selected; therefore, management and domestication are two intimately linked factors. Forms of management generally influence domestication, and it is through them that explaining this process among Amazonian plants is intended. Generally, the more elaborate the management demands of a plant, the greater its degree of domestication. In the case of Amazonian plants, depending on

the degree of management to which they may be submitted, they may be classified as (1) collected, (2) protected or planted with little human interference, and (3) planted with high human interference. There is also another distinct group – those managed unconsciously due to interference in the environment by humans for other purposes or due to dispersion of seeds through feces and/or discarding of nonedible parts.

Plants that are simply collected are left in their natural habitat without selection for any characteristic, and even if the fruits collected from more productive and better plants should be more disseminated, there is no reproductive isolation and presumably the population maintains itself stable. The word “presumably” is used because no matter how subtle, human occupation is capable of introducing some modification in the natural populations of plants. The reduction, through hunting, of frugivorous animals such as agoutis (*Dasyprocta leporina* L., *D. prymnolopha* Wagler, and *D. fuliginosa* Wagler), pacas (*Agouti paca* L.), and bats, which prey on and disperse seeds, may favor the increase in density of a certain species where the more productive plants might have greater chances of increasing the frequency of their alleles in a given location due to the increase in their density. The group of useful plants collected in the forest for medicinal purposes, food, or some other use may possibly comprise more than 1000 species.

The plants protected or planted with low human interference are those that occur naturally in the habitat and that are preserved during felling and later cared for or planted along trails or in clearings but that receive little care (Table 1). Examples of plants protected from burning include the tucumã (*Astrocaryum aculeatum* G.F.W. Meyer and *A. vulgare* Mart.) and inajá (*Attalea maripa* (C. Serra) Drude) palms. Plants under low human interference are those generally cast along trails and in clearings, as is done by the Kayapó Indians, who collect seeds and plantules of useful trees and plant them along trails on which they usually travel or in clearings opened by tree falls (Kerr and Posey, 1984). They generally belong to the same habitat and although they undergo some selection, reproductive isolation, as in the previous case, is not efficient because these species also occur in forests and can interbreed. Occasional progress in the domestication process may be achieved because the selected plants, when planted together, have greater chances of intercrossing, which facilitates the maintenance of a higher frequency of the alleles selected. Since isolation is not very efficient, progress is very slow. This group is prone to receive greater human influence than is the case with the previous group because their density and fecundity are in most cases favored by the reduction of competition with the other plants. The reproductive isolation of these species, although more efficient than in the previous group, is also not very efficient and there is no directional selection of the plants; they are simply spared.

The dispersion of those planted with high human interference (Table 2) is consciously done by humans and during their entire productive cycle they receive care and make up three distinct groups, according to the position they assume in the ecological succession of forest regeneration after burning. This succession is directed by humans toward a final floristic composition with a greater density of useful species than would be found in a forest without any history of human

Table 1 Protected or planted plants at low levels of human care^a

Names: English/Portuguese/Spanish	Latin name	Uses
—/caruru azedo/—	<i>Amaranthus cruentus</i> L.	Leaves as vegetable
Star nut palm/tucumã do Amazonas, tucumã- açu/chambira	<i>Astrocaryum aculeatum</i> G. F. W. Meyer	Fruit, fibers from leaves
—/tucumã-do-pará/aouará, awarra	<i>Astrocaryum vulgare</i> Mart.	Fruit, fibers from leaves
Brazil nut/castanha-do-pará/nuez del Brasil	<i>Bertholletia excelsa</i> Humb. Et Bonpl.	Nuts, infusion of fruits as a medicinal
Wild cherry/muruci verdadeiro/Indano, nanci, yoco	<i>Byrsonima crassifolia</i> L. Rich.	Fruit
Pekea/piquiá verdadeiro/amêndoa-do peru, al-mendro	<i>Caryocar villosum</i> (Aubl.) Pers.	Fruit, and oil from the pulp
—/castanha-de-porco/—	<i>Caryodendron amazonicum</i> Ducke	Seed as a nut
—/—/—	<i>Celosia argentea</i> L.	Leaves as vegetable
—/castanha-de-cutia/—	<i>Couepia edulis</i> Prance	Fruit
—/pajurá/—	<i>Couepia bracteosa</i> Benth.	Seeds as a nut
—/castanah pêndula/—	<i>Couepia longipendula</i> Pilger	Seeds as a nut
—/sorva, sorvinha/—	<i>Couma utilis</i> Muell. Argov.	Fruit
American oil palm/caiaué/noli, palma brasileira, carocito, colorada, palmiche	<i>Elais oleifera</i> Cortés	Oil from the pulp and endosperm, seed kernel for crafts
—/uxi/—	<i>Endopleura uchi</i> Cuatr.	Fruit
Wild coriander/chicória, coentro do pará/siuca culantro	<i>Eryngium foetidum</i> L.	Condiment
Assai palm/açaí/chonta, husaí	<i>Euterpe oleracea</i> Mart.	Fruit, trunk for building
—/mangaba/mango jsú	<i>Hancornia speciosa</i> Gomes	Fruit
Copal/jatobá/copalhuallo	<i>Hymenaea courbaril</i> L.	Fruit
—/ingá-açu/—	<i>Inga cinnamomea</i> Benth.	Fruit
Ice cream beam/ingá-cipó/guamo, guabo	<i>Inga edulis</i> Mart.	Fruit
Pataua/pataua/bataua, chapil, palma sege	<i>Oenocarpus bataua</i> (Mart.) Burr.	Fruit
Barbasco/timbó/barbasco	<i>Lonchocarpus utilis</i> Smith	Poison for fishes
—/maçaranduba, maçaranduba verdadeira/—	<i>Manilkara huberi</i> (Huber) Standl.	Fruit, edible latex
Mauritia, moriche/buriti, miriti/aguaje	<i>Mauritia flexuosa</i> L.	Fruit, sap as sweet sirup, starch from the trunk
—/bacaba açu, bacaba verdadeira/ungurauy, camou, manoco	<i>Oenocarpus bacaba</i> Mart.	Fruit, trunk for building, leaves to cover houses
—/bacaba-de-leque/—	<i>Oenocarpus disticus</i> Mart.	Fruit, trunk for building, leaves to cover houses
—/bacabi/mapora	<i>Oenocarpus mapora</i> Karsten	Fruit
—/bacabinha/—	<i>Oenocarpus minor</i> Mart.	Fruit
—/feijão macuco/—	<i>Pachyrhizum tuberosum</i> Lam.	Tubers as vegetable
—/pajurá-da-mata/—	<i>Parinari montana</i> Aubl.	Fruit
Wild passion fruit/maracujá suspiro, maracujá-de-rato, maracujá-do-mato/—	<i>Passiflora nitida</i> H. B. K.	Fruit
—/camapu/—	<i>Physalis angulata</i> L.	Fruit as a vegetable, roots as medicine
Backuri/bacuri/bacuri, matazona	<i>Platonia insignis</i> Mart.	Fruit
—/umari, mari gordo/—	<i>Poraqueiba paraensis</i> Ducke	Fruit
—/umari, umari do Amazonas/—	<i>Poraqueiba sericea</i> Tul.	Fruit
Canistel/cutite/caimo, canistel, yema de huevo	<i>Pouteria macrophylla</i> (Lam.) Eyma	Fruit
—/ucuqui/—	<i>Pouteria ucuqui</i> Pires et Schultes	Fruit
—/araça-pera/—	<i>Psidium acutangulum</i> DC	Fruit
Guavas/goiaba/guayaba	<i>Psidium guajava</i> L.	Fruit, medicinal tea from young leaves for diarrhea
—/araçaí, araça-do-campo/—	<i>Psidium guianensis</i> Swartz	Fruit
—/bacuripari liso/—	<i>Rheedia brasiliensis</i> (Mart.) Pl. et Tr.	Fruit
—/bacuripari/pacuriguazu	<i>Rheedia macrophylla</i> Pl. et Tr.	Fruit
Hog plum, plum bush/taperebá, cajamirim, cajá/mombim	<i>Spondias mombin</i> L.	Fruit, infusion from the bark for leucorrohea
—/pitomba/carayá-vola	<i>Talisia esculenta</i> (St. Hil.) Radlk.	Fruit
Cocoa, chocolate tree/cacau/cacao	<i>Theobroma cacao</i> L.	Fruit
Cupuassu/cupuacu, cupu, cupuácu verdadeiro/copoazur	<i>Theobroma grandiflorum</i> (Willd. ex Spreng.) Schum	Fruit
—/cacauí/cacau sacha, chocalatillo	<i>Theobroma speciosum</i> Willd.	Fruit

^aThey receive some influence on the genetic structure of their population. The domestication process is accepted as being in progress but at a very early stage. Some of these species were possibly undergoing a more advanced process of domestication, but a possible retrocession on their status is accepted due to loss of varieties or by the people who used them.

Table 2 Cultivated plants under a high level of human assistance^a

Names: English/Portuguese/Spanish	Latin name	Uses
Cashew/caju/marañón	<i>Anacardium occidentale</i> L.	Fruit, infusion from the bark for leucorrohea
Pineapple/abacaxi, ananas/piña	<i>Ananas comosus</i> (L.) Merrill.	Fruit, fiber from leaves
Soursop/graviola/guanábana, anona	<i>Annona muricata</i> L.	Fruit, infusion from the leaves for snake bite
Peanut/amendoim/mani	<i>Arachis hypogaea</i> L.	Seeds
Peach palm/pupunha/pejibaye, pijuayo, chontaduro	<i>Bactris gasipaes</i> H. B. K.	Fruit, trunk for building
Anatto/urucum/achiote	<i>Bixa orellana</i> L.	Arielle from seeds as colorant and condiment, largely used for painting the body
Guinea arrow root/ariá/dale dale	<i>Calathea allouia</i> (Aubl.) Lindl.	Tubercle
—/—/—	<i>Canna edulis</i> Ker.	Tubercle
Sweet pepper/pimenta-doce/aji	<i>Capsicum anuum</i> L. var. <i>minimum</i>	Fruit as a vegetable, condiment, medicinal
—/—/—	<i>Capsicum chinense</i> Jacq.	Condiment
—/pimenta-de-cheiro/—	<i>C. brasiliense</i>	Condiment
—/pimenta comari/—	<i>C. baccatum</i> L.	Condiment
Papaya, paw paw/mamão/lechosa, melon zapote	<i>Carica papaya</i> L.	Fruit
—/cupa/—	<i>Cissus gongyloides</i> Burch	Liana as vegetable
Calabash gourd/cuieira/pati	<i>Crescentia cujete</i> L.	Fruit domestic appliances
Yam/cará/sacha-papa	<i>Dioscorea trifida</i> L.	Tubercle
—/jaboti/—	<i>Duguetia stenantha</i> R. E. Fries	Fruit
—/araça-boi/arazá, araza buey	<i>Eugenia stipitata</i> McVaugh	Fruit
Coca/Amazon coca/ipadu/epadu	<i>Erythroxylum coca</i> Lam. var. <i>ipadu</i> Plowman	Leaves, stimulant, hunger and fatigue relief
Genipa/genipapo/huito	<i>Genipara americana</i> L.	Fruit
Cotton/algodão brabo/algodón	<i>Gossipium barbadense</i> L.	Fiber
Sweet potato/batata doce/camote	<i>Ipomoea batatas</i> (L.) Lam.	Tubercle
Manioc/mandioca/yucca	<i>Manihot esculenta</i> Crantz	Tubercle, leaves as vegetable
Arrowroot/aráruta/—	<i>Marantha arundinacea</i> L.	Tubercle
Tobacco/tabaco/tabaco	<i>Nicotiana tabacum</i> L.	Leaves that are smoked or smashed as stimulant
Passion fruit/maracujá, maracujá, verdadeiro/granadilla	<i>Passiflora edulis</i> Sims. f. <i>flavicarpa</i> Deg.	Fruit for a refrigerant and as a carminative
Giant granadilla/maracujá-acú, maracujá mamão/granadilla, granadilla real	<i>Passiflora quadrangularis</i> L.	Fruit
Guarana/guaraná/cupana	<i>Paullinea cupana</i> H. B. K. var. <i>sorbilis</i> (Mart.) Duce and var. <i>typica</i>	Seeds for infusion used as refrigerant and stimulant
Lima bean/feijão lima/—	<i>Phaseolus lunatus</i> L.	Beans
—/cucura, mapati/uvilla	<i>Pourouma cecropiaefolia</i> Mart.	Fruit
—/abiu/caimito	<i>Pouteria caimito</i> (Ruiz et Parvon) Radlk.	Fruit
Sapote/sapota-do-peru/zapote, mame colorado	<i>Quararibea cordata</i> (H. B. K.) Vischer	Fruit
—/biribá/—	<i>Rollinia mucosa</i> (Jacq.) Baill.	Fruit
—/cubiu/cocona	<i>Solanum sessiliflorum</i> Dunal.	Fruit as a vegetable
Para cress/jambu/jambu	<i>Spilanthes acmella</i> (L.) Murr.	Leaves as vegetable
—/cacau-do-peru/macambo	<i>Theobroma bicolor</i> Humb. & Bopl.	Fruit, toasted seeds as a nut
Cocoyam/taioaba/uncucha, malanga	<i>Xanthosoma sagittifolium</i> (L.) Schott.	Tubers and leaves as a vegetable
Corn, maize/milho/mayz	<i>Z. mays</i> L.	Seed as a grain, estiles as medicinal

^aThe domestication process is accepted as being in an advanced stage.

influence (Denevan *et al.*, 1984; Anderson and Posey, 1989; Balée, 1989). The first group is that of the most domesticated species: These are annual plants that are colonizers and fast growers, with a high productivity of edible biomass. They are manioc (*M. esculenta* Crantz), corn (*Z. mays* L.), and more recently, beans of the genus *Vigna*. The second group is formed by semiperennial species, sown after the plants in group 1: sweet potato (*Ipomoea batatas* (L.) Lam.), arrowroot (*Marantha arundinacea* L.), peanut (*Arachis hypogaea* L.), lima bean (*P. lunatus* L.), cará yam (*D. trifida* L.), and pineapple (*Ananas comosus* (L.) Merrill). Those of the third group are arboreal

species, generally fruit producers with rapid growth and the capacity for growing well in soils already leached by rains and exhausted by annual crops. These plants have a high capacity for production and deposition of their leaf biomass. They usually live for 20 years, but some of them live for 80 years, and cannot bear competition with other trees of the forest. They are peach palm (*Bactris gasipaes* H.B.K.), cucura (*Pourouma cecropiaefolia* Mart.), umari do Amazonas (*Poraqueiba sericea* Tul.), and biribá (*Rollinia mucosa* (Jacq.) Baill). Also in this group are other trees that do not have a great capacity for regenerating the soil but are still able to grow well in poor

soils: Guava (*Psidium guajava* L.), coca (*Erythroxylum coca* Lam. var. *ipadu* Plowman), and abiu (*Pouteria caimito* (Ruiz et Parvon) Radlk). After the planting of these categories, there is the reappearance of the group of plants protected/planted under low human interference. These make up the group in the final phase of regeneration in the direction of a climax forest. Sometimes, species of this group are planted, whereas others are only protected and require more specific ecological conditions, with some shading in the juvenile phase, humidity, and protection from heat. These plants are capable of competing with other trees of the forest and are part of the final climax stand achieved by the system; they are Brazil nut (*Bertholletia excelsa* H & B) and the piquiazeiros (*Caryocar villosum* Pers.), amapá doce (*Brosimum potabile* Ducke), maçaranduba (*Manilkara huberi* (Huber) Standl.), bacuri (*P. insignis* Mart.), cacao (*Theobroma cacao* L.), cacaú (*Theobroma speciosum* Willd.), and uxi (*Endopleura uchi* Cuatr.). Because trees of the climax forest and those of this group have the chance to make gene exchanges, diluting eventual gains in selection, they cannot be considered domesticated. It is curious to note that young Brazil nut trees are only seen in disturbed environments, but that in the climax forests they are frequent, which reinforces the hypothesis that the Brazil nut forests, such as those observed in the regions of southern Pará, Acre, and Alenquer, had once been various Indian agricultural plots. These useful forest trees form the so-called maçaranduba islands, Brazil nut islands, amapá-doce islands, bacuri islands, cacao islands, cacaú islands, uxi islands, and so on. When they begin to produce fruits, these islands begin to receive better care. The plants below the canopy are weeded to facilitate fruit collection and observation of game that also come searching for fruits. The Nambiquara Indians of the Hahaintesu have a curious system for transferring information on the localization of these "islands" from one generation to the next until they are ready to be exploited. The sites where they live are eventually abandoned, generally due to over-hunting or disease. The new site chosen is generally an old site that had been used because it had a water supply, offered some strategic defense position, and had trails enriched with useful plants. The former site has a cemetery. The tribe is divided into people: The "people of the curassow," "the jaguar," "the tapi," etc., and the individuals of each "people" have a specific cemetery where they should be buried. When Indians die, their companions take them to be buried in the cemetery of their respective people and thus they are able to visit the old sites, accompany the development of the "islands," and maintain their localization in tribal memory.

The groves of babaçu palms (*Orbignya martiana* Barb. Rod.), which occupy ~200,000 km² in Brazil and support ~450,000 subsistence-level households in the north, northeast, and central west regions of Brazil through their multiple products (fibers, thatch, basketry, construction, palm heart and fruits for oil, charcoal, and animal feed) are examples of unconscious management. This palm tree regenerates profusely when the primary forest is burned. The plant survives fire well because it has a unique germination process. Upon germinating, the seed sends its hypocotyl underground to a depth of about 10 cm and then growth of the gemule begins. It remains inside the soil, putting its leaves out above ground. When the forest is burned, the plants that are still in this phase

Figure 8 Nambiquara Indians of the Alantesu group enjoying fruits (not identified) recently collected from a fruiting plant in the savanna and scattering the seeds near a temporary hut built for support on one of their collecting journeys.

lose only their leaves but are capable of regenerating since the main bud is well protected from the fire. Owing to the reduction in competition with the other plants that were destroyed by fire, the babaçu plants end up dominating the environment (May *et al.*, 1985a, 1985b). Another example of unconscious management is the sowing of plants collected near the huts in piles of trash (Figure 8). This process is possibly what happened at the beginning of agriculture and the related sedentarism (Harlan, 1975). The plants thus unconsciously cultivated end up being cared for and recruited within an agricultural system.

All these systems of management and consequent selection have been applied since before the discovery to the present by the indigenous people, later by the caboclos, and recently by Japanese immigrants to Amazonia (Saragoussi *et al.*, 1988). This has maintained the preservation of already domesticated plants and their varieties and even the appearance or improvement of others. The Japanese farmers of Tomé-Açu and Castanhal and their descendants, using only massal selection, have been able to achieve better cultivars of cupuaçu (*T. grandiflorum* Schum.) and açaí (*Euterpe oleracea* Mart.). Virola softwood from the estuary islands of the Amazon River, which in the past was predated as a source of extractivism, today is wisely managed as a consequence of market forces, and thus is also undergoing domestication by caboclos.

Final Comments

A domesticated plant, it should be remembered, is in this state because humans brought about its domestication. If human-induced selection pressures cease, these plants will not survive, or their descendants will need to recompose their defenses to face competition in a natural environment and in doing so generally lose the attributes selected by humans (Harlan, 1975). Many of the indigenous cultivars were selected not only for flavor or productivity but also for mystical reasons and are thus susceptible to disappearance as a result of changes in habits. In Amazonia, the Indians are being besieged by pressures toward deculturation from the "civilized"

people who are occupying the region. In this process, much of the existing knowledge on plant use is lost. For medicinal plants, this loss is even greater since most of the time their usefulness is not visible, as in the case of fruiting species. With the gradual loss by the Indians of the properties and uses of the plants, everything may simply be considered “jungle.” Although Amazonia is considered one of the largest repositories of genetic resources in the world, there are still few efforts in recovery, collection, and evaluation of useful plants among the Indians. If humanity has these marvelous plants, delights in their flavor and their appearance, wears clothes and uses domestic utensils made from them, and uses them to cure pains and diseases, this is because the traditional peoples of Amazonia, very simple people, discovered them, selected them, and maintained them until now. Fortunately their rights were recognized by the Convention on Biological Biodiversity – The Nagoya Protocol on Access and Benefit-Sharing (Secretariat of the Convention on Biological Diversity, 2011), but the way to put it in practice is yet to be found.

Land-Use Changes and CO₂ Emissions Due to US Corn Ethanol Production

Wallace E Tyner and Farzad Taheripour, Purdue University, West Lafayette, IN, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Biofuels-induced land-use changes Production of corn ethanol causes a series of changes in the markets for feed, food, fuel, and many other commodities. In response to these changes, consumers adjust their demands for goods and services and producers alter their demands for intermediate and primary inputs and adjust their supplies with the new market conditions. In this process, the land-use change occurs through market-mediated effects as higher corn price due to higher demand induces farmers to increase corn production, which can lead to conversion of pasture or forest land to agricultural crop use land. When that land is used for agriculture, carbon stored either in the wood or in the soil is released, causing an increase in greenhouse gases.

BTU British Thermal Unit, a unit of energy equal to 1 055.06 joules.

GREET The Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation Model by Argonne National Laboratory. This is a model used to calculate the direct GHG emissions for different biofuel pathways.

GTAP Global Trade Analysis Project. The name also refers to the computable general equilibrium model and the global data base used with the model. Both are available from the GTAP Center at Purdue University, www.gtap.org
Renewable Fuel Standard (known as RFS or RFS2) A US federal government mandate requiring certain quantities of four categories of biofuels to be used with the total reaching 136 billion liters (36 billion gallons) of ethanol equivalent by 2022.

Introduction

US ethanol production increased from 1.7 billion gallons (BGs) in 2001 to about 10 BGs in 2009. According to the Renewable Fuel Standard (RFS2) in the US Energy Independence and Security Act of 2007 (CRS RL34294, 2007), US corn ethanol production would reach 15 BGs in 2015. This level of ethanol production would affect agricultural activities within USA and around the world. In particular, it can cause land-use changes anywhere in the world, and the implications of land-use changes are complex and controversial. Land-use changes associated with increased corn ethanol production are important because they can affect the CO₂ emissions associated with ethanol production and consumption.

The Argonne National Laboratory (ANL) (Wang, 1999, 2005) has developed a life cycle model, called "Greenhouse Gases, Regulated Emissions, and Energy Use in Transportation (GREET)", which estimates the emissions of greenhouse gases (GHGs, including CO₂, CH₄, and N₂O) of alternative fuels including corn ethanol production. The GREET model classifies GHG emissions into three categories: (1) feedstock production, (2) fuel production – corn to ethanol in this case, and (3) vehicle operation. The total emissions associated with the ethanol supply chain are then compared with the analogous calculations for gasoline. However, prior to this research, there was limited data on GHG emissions from land-use changes due to biofuel production included in the GREET model. Rather, the land-use consequences of biofuel production and their corresponding GHG emissions were highlighted in published articles showing that biofuel production could have extraordinary land-use implications that negated the seeming GHG benefits that had been calculated when land-use changes were not fully considered (Searchinger *et al.*, 2008 (henceforth referred to as SEA); Fargione *et al.*, 2008.)

This article reviews, summarizes, and synthesizes land-use changes and CO₂ emissions induced by US corn ethanol production for several alternative economic conditions and modeling assumptions. By combining land-use-related emissions due to ethanol production with net emissions calculated in GREET, it is possible to estimate total GHG emissions associated with corn ethanol production and use. This total can then be compared with gasoline to determine the net gain/loss for corn ethanol production and use compared with gasoline.

When the use of a crop, such as corn, is diverted from food or animal feed to feedstock for fuel, existing demand for the crop as a food or feed could cause new land to be brought into agricultural production to help meet at least some of the unmet demands. The amount of land so cleared can be estimated by using a computational general equilibrium (CGE) model of the global economy including agricultural commodities. For instance, the Global Trade Analysis Project (GTAP) model (Hertel, 1997) can be modified to assess the economic impacts of ethanol production and its land-use implications for the world under alternative sets of assumptions. (GTAP is a CGE model, which considers production, consumption, and trade of a wide range of goods and services by region and at a global scale).

The second step in determining the GHG impacts of a biofuel is to convert land-use changes, such as estimated in GTAP, into the associated CO₂ emissions. This is done using a module that generates CO₂ emissions factors that are used to convert land-use changes into CO₂ emissions. Such conversions depend on global inventories of carbon in soils and vegetation of different types of ecosystems globally. For instance, the Woods Hole Research Center data set on the soil and land cover carbon profiles divides the whole world into 10 regions and provides data on the soil and land cover carbon profiles for each region.

The third step in determining the GHG net emissions from a particular biofuel is to convert the land-use-related emissions into emissions per gallon of 100% ethanol and add these emissions to those calculated in GREET to get total emissions. This can be done either within the GREET model or by direct calculations.

Rather than using the terms “direct” and “indirect” emissions, as is commonly reported in the literature, this article categorizes the emissions as those calculated in GREET and thus associated with the use of corn for the production and combustion of corn ethanol and those associated with land-use changes that result from diverting the use of corn as a food and feed to its use as biofuel feedstock. By some definitions of the term “indirect,” the latter GHG emissions would be labeled “indirect” emissions. For clarity, this article labels them as emissions associated with induced land-use changes.

The Complexity and Global Nature of Land-Use Change

Land-use change is a complicated process. It is driven by many factors and varies through time. There are social as well as economic factors involved in land-use changes. The factors vary by culture, region, and economy (the authors are indebted to Gbadebo Oladosu and Keith Kline of Oak Ridge National Laboratory for providing data and useful perspectives on the land-use change process) and cannot be captured in a given analysis. This article focuses on the impacts of the RFS2 level of US corn-based biofuel production. Since corn is a globally produced and consumed commodity, this US policy of necessity has global impacts driven to a significant degree by changes in global supplies of and demands for food and feed grains. Use of a global general equilibrium model can capture many of these market-mediated effects.

The modified GTAP model is used to illustrate how to analyze the economic and environmental consequences of corn ethanol production. Then the simulations and assumptions

are discussed that are the basis for the land-use results predicted by GTAP. Next follows a discussion of the calculation of CO₂ emissions associated with this land use.

The evaluation of the impacts of US corn ethanol production on global land-use requires a model that is global in scope and links global production, consumption, and trade. In addition, the model should properly link energy, biofuel, and agriculture markets. Since biofuel, crop, and livestock industries compete through the land market, the model should link these activities through the land market as well. Furthermore, biofuel byproducts, which can be used in animal feedstuffs, bridge these industries. The connection between these industries through biofuel byproducts affects the nature of competition among these industries for land. All of these features are encompassed in a special-purpose version of the GTAP model and its database. This model will henceforth be referred to as GTAP-BIO-ADV (advanced GTAP-BIO model).

The GTAP model simulates the world economy using a global database that contains input-output tables for almost all countries. These tables provide detailed information on production and consumption of commodities and services along with investment and bilateral trade among regions. This database also includes payments to labor, capital, and land (for details, see Dimaranan (2006)). GTAP data come from a multitude of sources. The database also includes the most updated global land cover and land-use database by region disaggregated into 18 Agro-Ecological Zones (AEZs). These AEZs share common climate, precipitation, and moisture conditions. The land cover and land-use database is based on the Center for Sustainability and Global Environment (SAGE) database (for more information on the land-use database, see Lee *et al.* (2005)). The land-use database provides information on global crop yields as well. Version 6 of the GTAP database, which was used in this analysis, covers 57 groups of commodities and services for 87 countries and regions.

Taheripour *et al.* (2007) have expanded the GTAP standard database version 6 and explicitly introduced three biofuel commodities (ethanol from food grains and from sugarcane

Figure 1 Structure of consumption side of the GTAP-BIO-ADV model.

Figure 2 Production structure of GTAP-BIO-ADV.

and biodiesel from oilseeds) into it. *Birur et al. (2008)* have incorporated biofuels into the GTAP-E model. (GTAP-E was originally developed by *Burniaux and Truong (2002)* to incorporate energy into the GTAP framework, and has recently been modified by *McDougall and Golub (2007)*.) They augment the model by adding the possibility for substitutability between biofuels and petroleum products. **Figures 1 and 2** represent the structure of consumption and production sides of this model. In these figures, CES stands for constant elasticity of substitution, and CDE for constant difference elasticity and is the means of expressing household preferences in GTAP.

Figure 1 indicates that households could use biofuel as a substitute for petroleum products in GTAP-BIO-ADV. On the

contrary, **Figure 2** shows that at the bottom-most level of the production side, biofuels are a complement to petroleum products in the production process. It should be noted that in a general equilibrium model like GTAP, all the equations are solved simultaneously, so it is not a stepwise solution process.

Hertel et al. (2008) augmented this model with a land-use module to better depict the global competition for land among land-use sectors. The land-use module traces changes in the demand for land across the world at the AEZ level and thereby captures the potential for real competition between alternative land uses. In this module, land does not move across AEZs. However, the distribution of land across its alternative uses can change within each AEZ. Alternative uses

of land are as follows: forest, grassland, and cropland. In this module, livestock producers compete to use grassland, and there is competition among agricultural activities to use croplands. Corn falls in the category of coarse grains along with sorghum, oats, and barley. However, in the USA, this group comprises mostly corn. For example, in 2009, corn constituted 95.4% of the coarse grain production (by weight). Most of the remaining produce was sorghum, which also could be used for biofuels.

Recently, [Birur \(2010\)](#) added two new land categories of cropland pasture and unused cropland (e.g., retired cropland under the US Conservation Reserve Program (CRP)) into supply of land. [Figure 3](#) represents the new structure of land supply in the modified model.

In the new land supply, tree cropland pasture and unused cropland (mainly CRP) are explicitly defined as components of cropland. CRP land mainly generates environmental benefits. Hence, this type of land is introduced as an input into the sector that provides these services (i.e., Oth_Ind_Se). Cropland pasture is an input into the livestock industry. To facilitate transition of cropland pasture from livestock industry to crop production and vice versa, an industry is added to the model that uses cropland pasture as an input and sells its output (cropland pasture) to the livestock industry. This industry competes in the land market with crops. Finally, the livestock industry combines cropland pasture with pasture land in its production function, as shown in [Figure 4](#). This figure indicates that the livestock industry combines pasture

Figure 3 Land cover and land-use activities in the GTAP-BIO-ADV.

Figure 4 Production structure of the livestock industry.

land with cropland pasture in the value-added nest and uses feed and nonfeed inputs in its production function.

The land-use module determines expansion of cropland and its distribution among agricultural activities according to two important parameters: price elasticity of yield and ratio of productivities of marginal and average lands. The price elasticity of yield measures changes in crop yield due to the changes in crop price. In the simulations it was assumed that the price elasticity of yield is equal to 0.25. [Keeney and Hertel \(2008\)](#) have provided a detailed discussion on this parameter along with econometric evidence behind it.

The ratio of marginal and average productivities measures the productivity of new cropland versus the productivity of existing cropland. This ratio will henceforth be referred to as ETA (the Greek letter Eta). A set of regional ETAs at the AEZ level is obtained from a bio-process-based biogeochemistry model (terrestrial ecosystem model; [Zhuang et al., 2003](#)) along with spatially referenced information on climate, elevation, soils, and vegetation land-use data (for details see [Tyner et al., 2010](#)). Regional ETAs vary across the world and among AEZs.

[Taheripour et al. \(2010, 2011\)](#) added production, consumption, and trade of biofuel byproducts into the GTAP modeling framework, extending the original GTAP-BIO database ([Taheripour et al., 2007](#)) in several directions to better trace the links among biofuel, vegetable oil, food, feed, and livestock industries. Unlike the initial database, these articles distinguish between feedstock of the US and EU ethanol industries. The ethanol industry also produces distiller's dried grains with solubles (DDGS). They also split the "other food products" industry into two distinct industries: processed food and processed feed. In addition, they split the vegetable oil sector into two distinct industries: crude vegetable oil and refined vegetable oil. The crude vegetable oil sector uses oilseeds and produces crude vegetable oil (as the main product) and oilseed meal (as the byproduct). Unlike the original GTAP-BIO database, which directly converts oilseeds to biodiesel, they introduce a biodiesel production technology that uses crude vegetable oil and other inputs to produce biodiesel.

In addition, the latter article uses a three-level nesting structure for the demand for animal feedstuffs in the livestock industry, which brings more flexibility into this part of the model. [Figure 5](#) depicts this nesting structure. At the lower level of this nesting structure, DDGS and coarse grains are combined to create an energy feed. At this level, oilseeds and oilseed meals are combined to create a protein feed as well for countries that use oilseeds directly as feed. At a higher level, the protein and energy feed ingredients are combined. At this level, other crops also are bundled together. The livestock industry receives some inputs from processed livestock industry as well, and these materials are bundled together at the second level, too. Finally, all feed ingredients are combined to create the feed composite.

[Taheripour et al. \(2011\)](#) assigned elasticities of substitution to the different components of the demand for feed to replicate changes in the prices of DDGS and meals in USA and the EU during the time period 2001–2006. In addition, they did several experimental simulations and sensitivity tests to reach displacement ratios between DDGS, grains, oilseeds, and oilseed meals according to the literature in this area. Since oilseeds and oilseed meals are good substitutes in some

Figure 5 Structure of the nested demand for feed in livestock industry.

Table 1 Cost shares of major feed items in the US livestock industries in 2001 and 2006^a

Feed items	2001			2006		
	Dairy	Meat ruminant	Nonruminant	Dairy	Meat ruminant	Nonruminant
Coarse grains	67.6	68.4	82.9	61.0	57.5	82.5
Other crops	6.4	10.4	2.9	6.0	9.8	2.7
DDGS	5.6	6.4	1.1	12.9	17.6	2.1
Oilseeds meals	20.3	14.9	13.1	20.1	15.0	12.7

^aProcessed feed is dropped from this table to highlight shares of items listed in the table.

regions, they applied a relatively high elasticity of substitution, 20, between these two feed materials for all types of animal species. Following the literature, they used values of 25, 30, and 20 for the elasticities of substitution between coarse grains and DDGS in the dairy farms, other ruminant, and non-ruminant feed structure, respectively. They also applied a small value, 0.3, for the elasticity of substitution between the energy and protein feedstuffs because DDGS could displace a portion of meals in some feed rations, as shown in *Arora et al. (2008)* and *Fabiosa (2009)*. In the composite of other crops and composite of processed livestock inputs, they applied elasticities of substitution of 1.5 for all types of livestock industry. Finally, following *Keeney and Hertel (2005)*, they used elasticity of substitution of 0.9 at the higher level of the feed demand nest.

This article uses some GTAP simulation results to show how these elasticities shape the cost structure of the livestock industry. To accomplish this task, it uses the results obtained from the simulations introduced in its next section. In particular, it uses the results of the first simulation of the second group of experiments. This particular simulation replicates transition of the global economy from 2001 to 2006. The results of this simulation predict that the cost shares of coarse grain, other crops, and meals in the US livestock industries declined during the time period 2001–2006, whereas the cost share of DDGS increased. The largest substitution is DDGS for coarse grains, but there is also substitution for other crops and oilseed meals, depending on the livestock species. Note that

processed feed was dropped from the list of animal feeds to highlight the changes in the shares of crops, DDGS, and meals during this time period (*Table 1*).

Global markets (including agriculture) are complex and highly linked. This complexity and these linkages make it difficult to accurately estimate how a market perturbation, such as the use of sufficient US corn to produce 15 BG of ethanol, would impact land clearing and other aspects of land-use change around the world. This discussion indicates how a CGE model of the global agricultural economy has been structured to allow it to make such a prediction. In particular, the GTAP-BIO-ADV model and its database described earlier in this section and in the associated references have the following features:

1. It covers production, consumption, and trade of three types of biofuels: ethanol from crops and from sugarcane, and biodiesel from crude vegetable oil.
2. Byproducts are DDGS and oilseeds meals.
3. The crude vegetable oil industry uses oilseeds and produces crude vegetable oil and oilseed meals.
4. The biodiesel industry uses crude vegetable oil to produce biodiesel.
5. The demand for feedstuffs follows a three-level nesting structure.
6. The land module handles two new land categories of unused cropland and cropland pasture. Although the model could trace changes in these two groups of land

across the world, there are data on cropland pasture for the USA and Brazil and data on CRP only for the USA.

7. ETA has been calibrated for each AEZ and region instead of using the globally fixed ETA parameter as in the past.
8. Energy demand and supply elasticities have been recalibrated for this version.
9. The world economy is divided into 19 regions, 34 groups of commodities and services, 32 industries, and five groups of endowments.
10. When US ethanol is shocked, the production of other biofuels is held constant.

GTAP Simulations and their Results

This article will now consider the results of three different sets of analyses. In the first group, it follows the approach used in *Tyner et al. (2009)*. In this approach, the land-use implications of US ethanol production off the 2001 database are calculated. This approach isolates impacts of US ethanol production from other changes that shape the world economy. This method assumes that other factors such as population growth, yield improvement, and economic growth do not affect the land-use implications of producing more ethanol from agricultural resources. *Hertel et al. (2010)* provide more insights into this approach. Even though we use the 2001 starting point, the results are different from the results reported in *Tyner et al. (2009)* because a new model is used that includes all the changes described above.

In the second approach, a baseline that represents changes in the world economy during the time period 2001–2006 was constructed. Then the land-use impact of US ethanol production off the updated 2006 database was calculated, while following the principles of the first group of simulations for the time period 2006–2015. Finally, in the third approach, the updated 2006 database obtained from the second group of simulations was used, but it was assumed that during the time period 2006–2015, population and crop yields will continue to grow. These are two important factors that could alter the land-use impacts of ethanol production in the future. These three groups of simulations and their results are described in the rest of this section.

Group 1: Simulations with No Economic and Yield Growth and 2001 Base

The land-use implications of the US ethanol production for the following six production segments were calculated:

- Ethanol production from 2001 to 2006 level.
- Ethanol production from 2006 level to 7 BGs.
- Ethanol production from 7 to 15 BGs by increments of 2 BGs.

The global biofuel industry has followed a rapid growth path during the time period 2001–2006. The historical observations from this time period have been used to calibrate the biofuel parameters of the model (*Hertel et al., 2008*). Then gradual increases in the production of US ethanol after 2006 have been considered to evaluate marginal impacts of ethanol production. For this purpose, first the US ethanol production is increased from its 2006 level (4.855 BGs) to 7 BGs. Thereafter, ethanol production is increased by increments of 2 BGs to achieve the goal of 15 BGs in 2015.

Table 2 summarizes the land-use changes from the first set of simulations. These results indicate that producing 13.23 BGs of ethanol (from the 2001 production level to 15 BGs) requires about 2.96 million ha of additional land, of which 1.01 million ha (34%) are expected to be in the USA, with the remainder (1.95 million ha) in other regions (66%). This result suggests that the land-use changes due to US ethanol production will mainly take place outside the USA. Results from this group of simulations also indicate that the size of required land to achieve the 15 BGs of ethanol production is much smaller than the land-use changes suggested by a simple calculation that ignores important factors that could mitigate land-use impacts of ethanol production. (One can determine the land requirement for US ethanol production by multiplying corn yield (370 bushels per hectare of land) by a corn-to-ethanol conversion factor (e.g., 2.7 gallons per bushel of corn) and by the target for ethanol production. Based on this simple calculation, increasing ethanol production from its 2001 level (1.77 BG) to 15 BG needs about 13 million ha of land.) Several factors mitigate the land-use consequences of ethanol production. Among them are less corn consumption in the livestock industry due to use of more DDGS in the livestock industry, reductions in output of the livestock industry, reallocation of croplands across the world among alternative crops, and higher yields in crop production

Table 2 Global land-use changes due to the US ethanol production: off the 2001 database

Changes in US corn ethanol production	Land-use changes (ha)			Distribution of land use changes (%)			Hectares per 1000 gallons
	Within USA	Other regions	World	Within USA	Other Regions	World	
3.085 BG (2001–2006)	227,982	382,394	610,376	37.4	62.6	100.0	0.20
2.145 BG (2006–7 BG)	162,558	297,766	460,324	35.3	64.7	100.0	0.21
2.000 BG (7–9 BG)	152,990	295,051	448,041	34.1	65.9	100.0	0.22
2.000 BG (9–11 BG)	154,018	310,639	464,657	33.1	66.9	100.0	0.23
2.000 BG (11–13 BG)	154,706	325,639	480,345	32.2	67.8	100.0	0.24
2.000 BG (13–15 BG)	155,000	340,311	495,311	31.3	68.7	100.0	0.25
13.23 BG (2001–15 BG)	1,007,253	1,951,800	2,959,053	34.0	66.0	100.0	0.22

due to higher prices. Hertel *et al.* (2010) provide decomposed contributions of these factors in mitigating the land-use impacts of ethanol production.

The land required to increase the US ethanol production from its 2001 level to 15 BGs obtained from these simulations is smaller than its corresponding value reported in Tyner *et al.* (2009) by about 16.7% (i.e., 2.96 vs. 3.55 million ha). Two major modifications in the GTAP model contribute to this reduction. A portion of this reduction is associated with the land conversion factors. As noted earlier, a new set of regional land conversion factors at the AEZ level is used in this work. The new land conversion factors in several AEZs are higher than the single conversion factor of 0.66, which was used in earlier work (for details see Tyner *et al.*, 2010).

Introducing the new land categories (cropland pasture and unused land) (in these simulations, the area of US CRP land is held constant) into the model also contributes to the reduction in land requirement. In particular, in the USA and Brazil, in the presence of cropland pasture, farmers convert a portion of this type of land to crop production. For example, an increase in US ethanol production from its 2001 level to 15 BGs leads to the conversion of 1.2 million ha from cropland pasture to cropland. Indeed, a portion of this land conversion prevents sharp reductions in production of other crops. It is important to note that the competition between crop and livestock industry prevents full conversion of cropland pasture to crop production. These two modifications not only reduce the land requirement of ethanol production, but also alleviate the adverse impact of ethanol production on the prices and consumption of crops.

Table 2 also indicates that the required land for producing 1000 gallons of ethanol grows with higher levels of ethanol production. For example, for the 2001–2006 simulation, an additional 3.085 BGs of ethanol triggers global land-use changes of roughly 610 ha. This is equal to 0.20 ha per 1000 gallons of ethanol. However, for the 13–15 BGs simulation, an additional 1000 gallons of ethanol requires 0.25 ha of land. To increase ethanol production from the 2001 level to 15 BGs, on average about 0.22 ha of land per 1000 gallons of ethanol are required. The marginal level (0.25) is higher than the average (0.22), which would be expected because as more land comes into production, the yields on the incremental area would be lower.

Table 3 depicts another aspect of the land-use implications of US ethanol production. This table shows the distribution of

land-use changes between forest and grassland. About 25% of the required croplands needed to increase ethanol production from its 2001 level to 15 BGs come from forest, and the remaining (75%) come from grasslands. Table 3 also indicates that with higher levels of ethanol production, the portion of forests in the converted land into crop production increases very slightly (from 23% in 2001 to 25% at the 15 BGs ethanol production).

In the absence of crop yield growth, the increasing global land-use change, given equal increments of US ethanol production, is explained by the differences in the productivity of available lands. Productive lands are employed first before marginal lands, which have lower productivity and lower yields. At low levels of production, more productive lands are available; hence, less land is required to produce additional ethanol. However, at higher levels of ethanol production, most of the productive land is already being used, and only marginal land is available. Given this, more marginal land is required to produce the same increment of US corn ethanol production.

Group 2: Simulations with Updated Baseline for the Time Period 2001–2006

The global economy changed significantly over the 2001–2006 period. Countries followed different economic growth paths, population increased everywhere at different rates, land productivity rapidly increased in many regions (with some exceptions), and technology improved in many areas. These are important factors that could alter the land-use implications of biofuels. In the second group of simulations, these factors are taken into account.

To accomplish this task, a database was developed to include data on crop production, harvested area, forest areas, gross capital formation, labor force (skilled and unskilled), gross domestic product, and population for the whole world at the country level. Table 4 contains the percentage changes in macroeconomic variables (for details see Tyner *et al.* (2010)). Then this data set was used to generate a baseline that replicates the transition of the global economy from 2001 to 2006, whereas global biofuel production during this time period was targeted in the presence of population, income, and yield growths. In building the baseline, the model was guided to replicate the historical paths of changes in harvested

Table 3 Global land-use changes due to US ethanol production: off the 2001 database

Changes in US corn ethanol output	Land-use changes (ha)			Distribution of land-use changes (%)		
	Forest	Grassland	Crop ^a	Forest	Grassland	Total ^a
3.085 BG (2001–2006)	– 143,716	– 466,652	610,376	23.5	76.5	100.0
2.145 BG (2006–7 BG)	– 114,409	– 345,912	460,324	24.9	75.1	100.0
2.000 BG (7–9 BG)	– 112,330	– 335,712	448,041	25.1	74.9	100.0
2.000 BG (9–11 BG)	– 116,795	– 347,864	464,657	25.1	74.9	100.0
2.000 BG (11–13 BG)	– 120,688	– 359,650	480,345	25.1	74.9	100.0
2.000 BG (13–15 BG)	– 124,151	– 371,156	495,311	25.1	74.9	100.0
13.23 BG (2001–15 BG)	– 732,089	– 2,226,946	2,959,053	24.7	75.3	100.0

^aThe difference between the changes in cropland and the sum of forest and grassland is due to rounding. Cropland pasture is included in cropland.

areas across the world as well. Furthermore, changes in global forest area are traced to match the land use results with the historical changes in forest areas during the time period 2001–2006. Rates of technological improvements were adjusted to trace changes in cropland and forest areas. **Table 5** contains the cumulative yield change for each region and crop category over the 5 years.

To generate the 2006 baseline, the major macroeconomic variables are shocked according to the historical observations for the time period 2001–2006. In particular, GDP, gross capital formation, labor force, and population are shocked at the regional level. The global biofuel outputs are also shocked according to actual observations for the same time period.

Table 4 Percentage changes in macroeconomic variables (2001–2006)

<i>Regions</i>	<i>Population</i>	<i>GDP</i>	<i>Skilled labor</i>	<i>Unskilled labor</i>	<i>Capital</i>

In addition to these shocks, the model is calibrated to replicate observed improvement in yield over the time period 2001–2006 by crop and by region. Finally, technological changes in input–output ratios are introduced to replicate regional changes in the harvested area during this time period. Furthermore, the model is calibrated to trace changes in forest area during the baseline time period. For the list of implemented shocks, see *Tyner et al. (2010)*. This experiment provides a new database that represents the world economy in 2006 in the presence of changes in the major drivers of the world economy. To separate out the impacts of the US ethanol program from other drivers of the world economy, this experiment is repeated without the US ethanol shock. The difference between the land-use implications of these two simulations gives us the impact of the US ethanol program for the said time period.

Then the updated 2006 database is used to evaluate the land-use impacts of increasing US ethanol from its 2006 level to 15 BG incrementally. **Table 6** summarizes the global land-use implications obtained from the second group of simulations.

The results obtained from the second group of simulations indicate that about 2.0 million ha of cropland are needed to increase ethanol production from the 2001 level to 15 BGs. This figure is smaller than its corresponding figure obtained from the first group of simulations by 31%. Two main factors contribute to this reduction. During the time period 2001–2006, crop yields were growing faster than the demands for crops in many regions. This reduced the size of land-use changes in this period. In this case, the land-use implications of US ethanol for the time period 2006–2015 is smaller than the corresponding figure of the first cases because crop yields are higher in the updated database.

In the second group of simulations, cropland pasture moves to crop production faster than in the first group of simulations. In the presence of economic growth, about 5.3 million ha of cropland pasture will move to crop production.

^aThe difference between the changes in cropland and the sum of forest and grassland is due to rounding.

Table 7 represents distributions of land-use changes between forest and pasture for the second group of simulations. In this group of simulations, on average about 33% of required land for ethanol production comes from forest land. This figure is higher than the corresponding figure of the first group of simulations (25%).

Group 3: Simulations with Crop Yield and Population Growth for the Time Period 2006–2015

Some advocates of the US corn ethanol program argue that crop yields will increase in the future such that this increase could eliminate the land-use implications of ethanol production. This argument neglects the impacts of the future changes in the demand for crops. Demands for crops could increase in the future due to several factors such as changes in population and income, dietary transition as poorer countries consume more meat, or technological progress. In other words, one cannot examine yield (supply) increases alone. One must also include assumptions about increases in crop demand as well. In the third group of simulations, impacts of changes in crop yields and demand are examined as important items that could determine demand and supply for crops and food products.

In the third group of simulations, population growth is introduced into the model as a proxy for food demand increase. It is assumed that population will continue to grow globally during the time period 2006–2015 at the annual growth rate of 2001–2006. It is also assumed that crop yield

will increase uniformly at 1% annually after 2006 in all regions and across all types of crops. Although 1% might seem small, it is actually a large number as it is applied in all regions and for all crops. Finally, it is assumed that the regional demands for forest products will increase according to their annual rates of 2001–2006. The latter assumption is made to maintain the long-run pattern in the outputs of forest products. These simulations also include all the changes incorporated in the baseline simulation of the second group of simulations.

To find the land-use impacts of the US ethanol program under these assumptions, simulations were done with and without US ethanol production off the 2006 updated database (obtained in the second group of simulations) for the time period 2006–2015. To understand the land-use implications of the US ethanol program under these assumptions, the land-use implications were first analyzed with no US ethanol production. **Table 8** indicates land-use changes due to the yield and population growth for USA, EU, Brazil, and other regions.

This table indicates that after 2006, the cropland areas of USA, EU, Brazil, and other regions would fall due to the simultaneous shocks in yield and population growth. This means that yield growth would dominate the demand growth for crops, and therefore the demand for cropland decreases everywhere. In addition to that, the yield growth contributes to higher levels of food consumption everywhere.

The simulation results indicate that consumption of crops and food products grow faster than population everywhere across the world. This indicates that the yield effect works through two channels: (1) reduction in crop land area needed

Table 8 Simulated global land-use changes due to population and yield growth after 2006 (figures are in 1000 ha)

13.23 BG (2001–15 BG)	419,811	1,303,516	1,723,327	24.4	75.6	100.0	0.13

to satisfy demand and (2) higher per capita consumption of food. This means that 1% yield improvement will not end with 1% reduction in cropland, even if there is no population growth.

The released croplands are going to forest to support the long-run growth in forest products. Note that as mentioned earlier, in this group of simulations it is assumed that the global forest sector will continue to grow according to its 2001–2006 growth rate.

After this discussion, impacts of adding biofuel shocks into this picture can be examined. In general, the US ethanol program in this group of simulations generated smaller land-use changes compared to the results of the second group of simulations. **Table 9** shows that under the assumptions of this group of simulations, about 1.7 million ha of cropland are needed to increase ethanol production from the 2001 level to 15 BGs. This figure is smaller than the corresponding figure obtained from the second group of simulations by 20%. For the earlier time segments, after 2006 the size of land requirement is significantly smaller than what was observed in the second group of simulations. For example, in this group of simulations, only 0.11 ha of cropland are needed to produce 1000 gallons of ethanol in the time period 2006–2007, whereas the corresponding number obtained from the second group of simulations is about 0.15.

As the year 2015 is approaching, the population growth is dominating the yield growth in some regions and the land requirement is growing. **Table 9** shows that the share of USA in land requirement is about 24% on average in this group of simulations.

The distribution of land-use changes between forest and pasture land is similar to that in the second group of simulations. The assumption on the regional demands for forest products drives this result. It is very important to note that adding income growth or changes in other economic factors into this picture may change the geographical distribution of land-use changes or the distribution of the land requirement for ethanol production between forest and grassland (**Table 10**).

Land-Use CO₂ Emission Factors

Emission factors are used to convert land-use changes into land-use CO₂ emissions. Land conversions of forest and grassland into crop production release CO₂ emissions from two sources: (1) direct CO₂ emissions from land conversion and (2) foregone CO₂ sequestration by forests. The direct CO₂ emissions consist of carbon stored in the vegetation and in the soil, which are released when forests or grasslands are cleared and converted into croplands. The foregone carbon

Table 10 Simulated global land-use changes due to US ethanol production: with yield and population growth after 2006

^aThe difference between the changes in cropland and the sum of forest and grassland is due to rounding.

Table 11 Estimated marginal land-use emissions per gallon of E100 for 13–15 billion gallons simulation (30-year payoff method)

Total 30-year emissions from land-use changes (million metric tons)	110.77
Change in ethanol production (million gallons) per year	2,000
Emissions (metric tons per gallon-year of ethanol)	0.0554
Emissions (grams per gallon-year of ethanol)	55,386
One year marginal emissions (grams per gallon of ethanol)	1,846

sequestration accounts for the amount of carbon that could have been stored from annual forest growth, if land had remained forested. This is the opportunity costs of cleared land in terms of its potential to store carbon.

As mentioned earlier (*see* Introduction) the Woods Hole data set (taken from the supporting documents of SEA) is relied upon to develop the land-use emissions factors. This data set divides the world into 10 homogenous regions, determines distributions of forests and grasslands within each region across different types of vegetation cover, and provides detailed information on the carbon stored in the vegetation and in the soil of forests and grasslands within each region.

The Woods Hole data set provides two key carbon figures for each type of land according to its natural vegetation. These figures are carbon stored in the soil and carbon stored in the vegetation. It is assumed that when a natural vegetation area (either forest or grassland) is converted to cropland, about 25% of the carbon stored in its soil will be released into the atmosphere. In addition, it is assumed that 75% of carbon stored in the forest-type vegetation and 100% of carbon stored in the grassland vegetation will be released into the atmosphere at the time of land conversion. (In essence, it is assumed that 25% of the carbon in wood is stored in buildings, furniture, etc.) If more than one type of vegetation is available in an area, the weighted average emissions for that area is calculated, where weights are shares of vegetation areas. The emission factors for forest areas and grasslands are calculated separately. Sensitivity analysis can be conducted on any of the data and assumptions used in this analysis.

Regarding forgone carbon sequestration, it is assumed that when a natural vegetation area is converted to cropland, it loses its carbon sequestration capacity as long as it is under crop production. Again, if more than one type of land is available, weighted average of forgone carbon sequestration is

used. The direct and forgone sequestration in each region are simply added. Hence, in each area, there are two groups of emission factors: forest and grassland emission factors. The emission factors are calculated based on the assumption that the converted land to crop production will remain under crop production for 30 years (for more details on emissions factors, see *Tyner et al. (2010)*). We recognize that the 30-year period is somewhat arbitrary. Thirty years roughly equals the life of a biofuel facility, so it seems as reasonable an assumption as any other.

At this point it is important to note that some research indicates that conservation tillage practices and enhanced rotation programs can increase the carbon sequestration ability of croplands. This means that using advanced technologies in corn production can increase carbon stored in soil (*West and Post, 2002*). This research ignores impacts of advanced tillage methods on the carbon sequestration ability of cropland.

Estimated Land-Use CO₂ Emissions Due to US Ethanol Production

This article now combines simulated land-use changes due to US ethanol production with the CO₂ release emission factors. This is a straightforward process. Suppose ΔLF_{rj} (*see* Tables 2, 6, and 9) is the size of change in land type *j* (*j*=forest and grassland) in region *r* due to *X* gallons of increase in the US ethanol production. In addition, suppose that the annual CO₂ emission factor for land type *j* in region *r* for a 30-year ethanol production is about F_{rj} . Then the global annual CO₂ emissions due to the production of *X* gallons of ethanol per year USA will be equal to

$$LUE_W = \sum_r \sum_j \Delta LF_{rj} F_{rj} \quad [1]$$

Using this approach, CO₂ emissions were calculated for all land-use simulation scenarios (three groups of simulations and six time segments) and for all emission factors derived from the Woods Hole data sets. Once emissions have been calculated, the marginal and average land-use emissions due to production of each gallon of pure ethanol (E100) can be calculated for all groups of simulations examined in this article. For example, *Table 11* shows how the marginal land-use emissions due to producing each gallon of E100 for the 13–15 BGs were calculated for the first group of simulations.

The value of 110.77 million metric tons of emissions presented in this table is obtained by multiplying regional forest and grassland changes due to an increase in ethanol production from 13 to 15 BGs by their corresponding Woods Hole annual emissions factors and then summed over regions. The result of this calculation is multiplied by 30 to present the magnitude of total emissions more than 30 years. The last row of this table shows the annual marginal land-use emissions of each additional gallon of ethanol when moving from 13 to 15 BGs.

Land Use Emissions for the First Group of Simulations

Table 12 represents marginal and average land-use emissions obtained from simulations off the 2001 database. This table indicates that marginal emissions are increasing in ethanol production. For example, although an increase in ethanol production from 7 to 9 BGs generates 1687 g CO₂ emissions per gallon of ethanol, moving from 9 to 11 BGs generates 1745 g CO₂ per gallon. When ethanol production reaches 15 BGs, each additional gallon of ethanol generates 1846 g of CO₂. **Table 12** indicates that average emissions are increasing in ethanol production as well. This table shows that during the time period 2001–2006, on average each gallon of US ethanol was generating 1477 g CO₂. However, if ethanol production reaches 15 BGs, on average each gallon of ethanol generates 1676 g of emissions. It is important to note that in this group of simulations, about 61% of emissions result from deforestation and 39% from converting grasslands into crop production.

Note that this article ignores impacts of the first 1.77 BGs of ethanol on the average land-use changes per gallon of ethanol production. Incorporating land-use changes due to the first 1.77 BGs of ethanol will moderately reduce the average emissions per gallon of ethanol.

Land-use emissions obtained from this group of simulations are smaller than the authors' earlier estimates of land-use emissions. For example, as shown in **Table 12**, on average each gallon of US ethanol generates 1676 g emissions. The corresponding number reported in *Tyner et al. (2009)* was about 2210 g emissions. This shows about 16.5% reduction in emissions per gallon of ethanol. This is due to the use of new regional ETAs and the incorporation of cropland pasture into the picture.

Land-Use Emissions for the Second Group of Simulations

Table 13 presents the marginal and average emissions for the second group of simulations, where land-use changes are calculated according to the updated baseline for 2001–2006. Emissions obtained from second group of simulations follow the pattern of the first group. However, their magnitudes are smaller than those of the first group.

As shown in **Table 13**, when the US ethanol production reaches 15 BGs, each additional gallon of ethanol generates about 1467 g of emissions. At this level of ethanol production, on average each gallon of ethanol generates 1426 g of CO₂ emissions. These figures are smaller than the corresponding figures of the first group of simulations by 21% and 15%. These reductions are due to yield improvement during the

2011–2013	2.000	1027	419	1446	11.23	994	424	1418
2013–2015	2.000	1040	427	1467	13.23	1001	424	1426

time period 2001–2006. Over this period, yield growth in some regions was faster than demand growth. It is important to note that in this group of simulations, about 70% of emissions come from deforestation and the remainder come from converting grasslands into crop production.

Land-Use Emissions for the Third Group of Simulations

Table 14 shows the marginal and average land-use emission for the third group of simulations, where land-use changes are calculated according to the simulations with the updated 2001–2006 database and population, yield, and forest product growth. As shown in **Table 14**, in this case during the time period 2006–2015, the marginal emissions grow when the population growth dominates the yield growth. For example, an additional gallon of ethanol produces about 1032 g emissions in the time period 2006–2007, whereas each gallon of additional ethanol produces 1159 g emissions in the time period 2013–2015. In this group of simulations, on average each gallon of ethanol generates about 1167 g of emissions. This figure is smaller than the corresponding figure obtained from the second group of simulations by about 18%.

Final Analysis

This article now compares the land-use emissions obtained from the three groups of simulations with the results of SEA. **Table 15** shows lower emissions due to land-use change when

all economic and demographic and yield growth are taken into account in the third group of simulations. The average value of the third group of simulations is about 13.6% of the original SEA result. The results of the first and second groups of simulations are approximately 20% and 16.6% of SEA.

Total Emissions from Production and Consumption of Ethanol

Table 18 contains the estimated well-to-wheel ethanol emissions for the marginal and average land-use changes for the three groups of simulations. (In this article, the direct marginal GHG emissions (i.e., nonland emissions) of ethanol for the post-2006 period are taken from 100% dry mill.) For the first group of simulations, the production and consumption of each gallon of ethanol (E100) on average generates about 6800 g of GHG emissions. In this case, about 24.6% of released emissions are related to land-use changes. When changes in population and other factors are incorporated, each gallon of ethanol (E100) on average generates about 6550 g of GHG emissions. In this case, about 21.7% of released emissions are related to land-use changes. Finally, in the third group, when the population and yield growth after 2006 are taken into account, production and consumption of each gallon of ethanol (E100) generates about 6291 g of emissions. In the third case, about 18.5% of released emissions are related to land-use change.

Table 16 indicates well-to-wheel ethanol emissions expressed as grams per gallon of ethanol and as grams per

Table 14 Annual marginal and average estimated land-use emissions due to US ethanol production: obtained from the simulations off the updated 2006 database and with population and yield growth after 2006

Time segment	Marginal emissions (grams CO ₂ per gallon of ethanol)				Average emissions (grams CO ₂ per gallon of ethanol)			
	Changes in ethanol production	Forest	Grasslands	Total	Total ethanol production	Forests	Grasslands	Total
2001–2006	3.085	925	465	1390	3.085	925	465	1390

	Average	1167	14.5	5124	6291	78.1

^aFrom GREET simulations. The default values were used in GREET version 1.3c for 2015 for the simulations. The marginal and average differ for ethanol direct emissions because the fraction that is wet vs. dry milling decreases over time, yielding slightly lower direct emissions for the marginal case.

^bLow heating values of gasoline and ethanol are: 116,090 and 76,330 BTU per gallon.

Table 17 Estimated well-to-wheel ethanol and gasoline emissions

Description		Emissions in grams per gallon of gasoline equivalent			Emissions (g MJ ⁻¹)		
		Ethanol	Gasoline	Ethanol vs. gasoline (%)	Ethanol	Gasoline	Ethanol vs. gasoline (percentage)
Simulations off the 2001 database	Marginal	10,564	11,428	92.4	86.3	93.3	92.2
	Average	10,342	11,428	90.5	84.4	93.3	90.5
Simulations off the 2006 database	Marginal	9,988	11,428	87.4	81.5	93.3	87.4
	Average	9,961	11,428	87.2	81.3	93.3	87.2
Simulations off the 2006 database plus population and yield growth	Marginal	9,520	11,428	83.3	77.7	93.3	83.3
	Average	9,568	11,428	83.7	78.1	93.3	83.7

megajoule (MJ). For the first, second, and third groups of simulations, production and consumption of each gallon of ethanol (E100) on average generates about 84.4, 81.3, and 78.1 g MJ⁻¹ emissions, respectively. Land-use emission for the third group of simulation is 14.5 g MJ⁻¹.

Finally, **Table 17** compares total emissions of E100 obtained from the three groups of simulations with the emissions of conventional gasoline. This table indicates that ethanol production induces lower emissions compared to conventional gasoline for all groups of simulations. For example, the total GHG emission due to production and consumption of E100 (including land-use emissions) obtained from the first group of simulations is about 10,342 g per gallon of gasoline equivalent for the average land-use changes. This figure is about 90.5% of the emissions due to production and consumption of conventional gasoline. When the updated 2006 database is used, the total estimated GHG emissions due to production and consumption of E100 is approximately 9961 g per gallon of gasoline equivalent for the average land-use changes. This figure is 87.2% of the emissions due to production and consumption of conventional gasoline. Finally, when the updated database is used, and population and yield increase after 2006 is assumed, the total estimated emission for E100 is 9568 g per gallon of gasoline equivalent for the average land-use changes. In this case, the E100 emission estimate is about 83.7% of emissions

associated with conventional gasoline. **Table 17** presents emissions of ethanol and gasoline in grams per gallon of gasoline equivalent and grams per megajoule.

Since the third group of simulations takes into account changes in population, crop yields, economic growth, and growth in primary inputs during the time period 2001–2006 and after that assumes that population and yield growth will continue, the emissions obtained from this group of simulations are lower than in other cases. However, the results are derived from authors' assumptions, in particular for the time period 2006–2015. Any change in these assumptions could alter the results. In other words, this article has assumed 1% global growth in yields for all crops and 2001–2006 population growth through 2015. Changes in these assumptions would alter the numerical results.

Conclusions

The overarching objective of this article has been to show how predictions of the global land-use changes induced by US corn ethanol programs critically depend on processes that have been overlooked in some studies. Although this is a controversial topic, the review and synthesis presented in this article suggest the following. First, with more than a third of the US corn crop today going to ethanol, it is simply not

Table 18 Summary of the different modeling results

Result	Original January 2009 estimates	Model improvements with 2001 database	Baseline updated to 2006	Updated baseline and growth in demand and yield
Land needed for ethanol (ha per 1000 gallons)	0.27	0.22	0.15	0.13
Distribution of land-use change between forest and pasture (%forest per %pasture)	23/77	25/75	33/67	33/67
Distribution of land-use change between USA and rest of the world (%US per %Others)	35/65	34/66	24/76	24/76
Average emissions of 15 BG program (grams CO ₂ per gallon of ethanol)	1931	1676	1426	1167
% of Searchinger <i>et al.</i>	22.5	19.5	16.6	13.6
Emissions per gallon gasoline equivalent (grams CO ₂ per gallon)	10,564	10,342	9961	9568
Emissions per MJ (grams CO ₂ per MJ)	86.3	84.4	81.3	78.1
Total ethanol emissions as % of gasoline	92.4	90.5	87.2	83.7

credible to argue that there are no global land-use change implications of corn ethanol. The valid question to ask is to what extent ethanol production will induce land-use changes. Second, given the uncertainty of underlying data and parameter estimation and the alternative assumptions that various models might make, one cannot escape the conclusion that predictions of land-use change are uncertain and, of course, are all obtained based on economic predictions. The estimation range depends on what is being simulated, as will be seen in the following paragraphs.

Numerous improvements have been made in the models used for the analysis. These improvements have been spelled out in this article and in other articles. There are better data on land productivity and on cropland pasture and CRP lands, and these data and associated parameters are now in the model. The treatment of livestock and livestock feed sectors has been improved. Similarly, these changes are reflected in the current version of the model. Data on crop yields and many other variables amass for every region of the world, and much of those data are used in this analysis and model calibration. These data and model improvements have significantly improved the analysis and model results.

Table 18 provides a convenient summary of the evolution of some of the results over the different versions of the model and data. The third column replicates the summary results from the January 2009 draft article before all the model changes described were implemented. The January 2009 results are provided only for reference, so the comparisons will be based on the three simulations reported in this article. The fourth column shows all the model improvements and the 2001 database. The fifth column reflects the baseline updated to 2006 as described in this article. The last column depicts the updated baseline to 2006 and the assumed growth in demand and supply as described in this article.

Ethanol emissions as a fraction of gasoline emissions range between 83.7% and 90.5%. In a recent analysis including uncertainty in GHG estimation using an earlier version of GTAP-BIO, Hertel *et al.* (2010) concluded that the corn ethanol-induced emissions from land-use change range between 2 and 51 g MJ⁻¹. The authors' estimate for the last case is 14.5 g MJ⁻¹. This large range taken from another study using similar approaches clearly illustrates the uncertainty inherent in this analysis. It also concludes that zero is not within the error bounds. In other words, emissions induced by land-use change are not zero, but measuring them with high precision is not yet possible.

Limitations of this Research

As indicated in this article, analysis such as that undertaken here is very complex and is limited by data availability, validity of parameters, and other modeling constraints. Economic models, like other models, are abstractions from reality. They can never perfectly depict all the forces and drivers of changes in an economy. However, the basic model used for this analysis, GTAP, has withstood the test of time and peer review. Hundreds of peer-reviewed articles have been published using the GTAP database and analytical framework. In this project, many changes have been made to the model and database to improve their usefulness for evaluating the land-use change impacts of large-scale biofuels programs. Yet uncertainties remain. This article has described the evolution of the modeling and analysis and presents openly the evolution of the results. It is believed quite strongly that analysis of this type must be done with models and databases that are available to others. Replicability and innovation are critical factors for progress in science. They also are important for credibility in policy analysis. This model is available at the GTAP website for GTAP subscribers.

Glossary

Animal unit month (AUM) Quantity of forage needed to sustain one 1000-lb cow or five sheep for one month.

Biological soil crusts Collective term referring to the combination of nonvascular and non-seed-forming plants that commonly occur on the soil surface of many arid and semiarid ecosystems. These crusts may consist of mosses, lichens, liverworts, green algae, and cyanobacteria. Synonyms: cryptogams, microfloral, cryptobiotic, cryptogamic, microbiotic, organogenic, biogenic, biotic, and microphytic soil crusts.

Browse That part of leaf, twig, and reproductive growth of shrubs, woody vines, and trees available for animal consumption. The act of consuming leaves, twigs, or reproductive parts of shrubs, woody vines, and trees.

Degradation Decrease in ecosystem productivity or structure, and/or declines in native species diversity (sometimes with concomitant increases in exotic species) due to land use practices. Directly related to declines in biodiversity, ecosystem degradation encompasses soil impoverishment (e.g., compaction, erosion, salinization, loss of biological soil crusts) and hydrological alterations that diminish water availability. Similar to desertification.

Desertification Process by which an area becomes more arid through the decline in primary productivity, elimination of biological cover, shifts in plant diversity, or degradation of soils due to human uses whose impacts exceed the sustainability of the landscape. Similar to degradation.

Forbs Non-graminoid herbaceous plants.

Graminoids Grasses (family Poaceae) and grass-like plants, mostly sedges (family Cyperaceae) and rushes (family Juncaceae).

Grazing Act of consuming herbaceous plants, including grass, grass-like plants, and forbs.

Overgraze Consumption of forage to the extent that declines in productivity or desirable species composition are probable (i.e., degradation). Overgrazing is excessive use in terms of the amount, duration, and frequency of plant utilization.

Pasture Lands in which the native vegetation has been removed in favor of cultivated grasses or other forage plants.

Range condition Current productivity and composition of plants on a rangeland relative to its ecological potential. Often range condition is classified into arbitrary classes (i.e., excellent, good, fair, and poor).

Rangeland Land on which the potential native vegetation is predominately grasses, grass-like plants, forbs, or shrubs. Rangelands include prairies, marshes, tundra, wet meadows, savannas, shrubland steppe, chaparral, desert grasslands, and woodlands.

Riparian zone Interface between streams and terrestrial uplands. These zones are three-dimensional areas of direct interaction between the terrestrial and aquatic ecosystems. They often contain unique species and high levels of biological diversity.

Ruminant Grazing mammal with a complex four-chambered stomach (including a rumen). Common ruminants include cattle, sheep, goats, deer, antelopes, and giraffes.

Savanna Ecosystem with a more or less continuous herbaceous layer dominated by graminoids and broad-leaved herbs with an overstory of trees or shrubs that covers less than 10% of the area. In contrast, grasslands are typified by a pure graminoid or herbaceous layer with no (or very few) tree or shrub elements that rise above the grass layer.

Woodland Ecosystem in which the mature overstory tree or tall shrub cover makes up 10 to 60% of the area. Typically, a well-developed herbaceous understory is present. Note: forests typically have a mature tree cover > 60%.

Rangelands of the World

Rangelands are defined as those lands where the native vegetation is predominantly grasses, shrubs, or open woodlands. Rangelands include grasslands, shrublands, savannas, open woodlands, and most desert, tundra (arctic and alpine), meadow, wetland, and riparian ecosystems. Occurring from the tropics to polar regions, rangelands cover more land area than any other type on Earth. Because of climatic or edaphic limitations, they tend to be lands that are incapable of growing marketable timber or agronomic crops without irrigation or some other modification (i.e., they are over poor-quality

soils and/or are too wet, too dry, or too cold for cultivation). The composition, structure, productivity, and diversity of these ecosystems are governed by a combination of climate, geography, topography, and geology, including soil development. In addition, rangelands are used by a large number of vertebrate and invertebrate herbivores, including a diverse combination of domestic or native ungulates.

Tundra

Tundra ecosystems are dominated by perennial grasses, forbs, shrubs, and biological soil crusts consisting of cyanobacteria,

Figure 1 The arctic tundra landscape of the Brooks Range, Arctic National Wildlife Refuge, Alaska, with permission from Boone Kauffman.

lichens, and mosses (Figure 1). These species can tolerate the climatic conditions of high latitudes or altitudes. Tundra ecosystems are generally set apart from forested ecosystems by a climatic tree line defined by the 10 °C isotherm for the mean temperature of the warmest month. Tundra plants are low in stature with growth buds near the soil surface, where temperature is less variable. The morphology of herbaceous plants are often cushion or rosette growth forms and lichens are usually a foliose form. Shrubs are low-growing with short internodes between leaves. Temperate alpine tundra communities have short growing seasons similar to those in arctic tundra. In contrast, tropical alpine tundra communities of Africa, South America, and Oceania exist in conditions of freezing or near-freezing temperatures each night, with day-time temperatures allowing for active plant growth throughout the year.

The important herbivores of the Arctic are rodents and ungulates. Lemmings (*Dicrostonyx* spp. and *Lemmus* spp.) can have great impacts on arctic ecosystems during years of high population densities. Lemmings exhibit different seasonal patterns of use within various parts of their habitats. During the winter, they use wetlands and graze the soil-level parts of plants while discarding the upper portions of the plants. This grazing pattern results in piles of graminoid litter known as lemming hay. During spring, lemmings move to south-facing slopes, where solar insolation results in the earliest available green biomass. During peak population cycles when densities are high, lemmings can consume between 20 and 70% of the available plant mass.

The dominant native ungulates in the Arctic include caribou or reindeer (*Rangifer tarandus*) and musk ox (*Ovibos moschatus*). Domestication of reindeer and musk ox has led to their introduction throughout the arctic tundra and to reindeer introduction into northern Antarctica. Alpine tundra provides seasonal habitat for wild ungulates, including elk, deer, red deer, mountain sheep, and mountain goats. Domestic livestock

breeds adapted to cooler environments are also present in various arctic or alpine tundra communities of the world (e.g., cattle, sheep, goats, horses, llamas, and yak).

Grasslands and Savannas

Natural grasslands, also known as campos, llanos, pampas, plains, prairie, steppe, and veld, are frequently associated with semi-permanent high air pressure systems and high amounts of solar radiation. Annual precipitation typically ranges from 160 to 1700 mm with distinct wet and dry seasons. Grasses or graminoids dominate the vegetation composition, with forbs being a secondary component and short-stature shrubs contributing a lesser amount. The grass (or graminoid) dominance of grasslands is the result of current climatic conditions and/or natural disturbance processes such as fire. With human degradation such as overgrazing or fire suppression, shrubs often increase in abundance. In the tropics and in temperate locations with summer precipitation, C_4 grasses (warm-season grasses) will predominate because of their optimal growth at warmer temperatures. Northern temperate locations, where moisture is most available when temperatures are cooler, favor C_3 grasses (cool-season grasses). Biological soil crusts frequently occupy the soil surface below or between the plant cover, particularly in drier desert grasslands.

In equatorial regions, tropical savannas are a dominant rangeland ecosystem. They form a transitional zone along a precipitation gradient from tropical rain forests to arid deserts. Dense grasslands with occasional trees and shrubs characterize tropical savannas. As in grasslands, distinct wet and dry seasons typify the climate of tropical savannas. Disturbances are a prevalent feature of savannas; during the dry season, lightning-caused fires may occur. Human-ignited fires are very common throughout the world and maintain the open nature of many tropical savannas. Fire-return intervals in savannas are among the most frequent of any landscape on Earth. It is estimated

Figure 2 Overview of the Brazilian cerrado. This is a mosaic of grasslands, savannas, and woodlands that have a high level of biotic richness. Note the fire in the background, which is a common disturbance in this ecosystem. Land conversion to cattle pastures, soybeans, and other croplands is occurring at alarming rates in this ecosystem, with permission from Boone Kauffman.

that 50–75% of the humid savannas of Africa and South America burn each year.

Tropical savannas are highly productive. Grass biomass in humid savannas (>700 mm precipitation yr^{-1}) averages about 6.6 Mg ha^{-1} in Africa and South America, and 4.9 Mg ha^{-1} in tropical Asia. In savanna-woodlands, aboveground biomass may be as high as $25\text{--}61 \text{ Mg ha}^{-1}$. Roots and other subterranean tissues account for the majority of the plant biomass in savannas and grasslands (de Castro and Kauffman, 1998).

Tropical savannas are also very species-rich. For example, the largest savanna type in South America is the Brazilian cerrado, which often contains over $400 \text{ species ha}^{-1}$ (Figure 2). Except for tropical rain forest, this is among the richest vascular plant assemblages on Earth. For example, about 3500 plant species and 400 bird species have been identified in the cerrado of the 5800 km^2 Federal District surrounding Brasília, the capital of Brazil.

Savannas can experience rapid changes in species composition and structure following the introduction of an anthropogenic perturbation. Changes in the patterns of fire are one example; fire suppression results in an increase in the dominance of tree and shrub vegetation. Conversely, increasing the occurrence of fire enhances grass abundance. Linkages between fire, grazing animals, disease, and vegetation structure were described by Sinclair (1979). He related how the elimination of a ruminant disease, rinderpest, was a perturbation that changed the structure and composition of landscapes within the Serengeti of Africa. The immediate effect of rinderpest elimination was an increase in wildebeest numbers. On the plains, increased grazing pressures reduced grasses and increased forbs. Grant's gazelle increased along with the forbs, thus leading to population increases in cheetah. In woodlands, grazing reduced the grasses, which in turn reduced the fuel to support fires. The reduction in grasses resulted in a

reduction in buffalo. Tree numbers then began to increase, which favored an increase in the giraffe populations.

Plants within natural temperate grasslands and tropical savannas vary in their tolerance to large numbers of grazing animals. The images of grasslands and savannas for many people include large herds of ungulates, such as bison (*Bison bison*) in the Great Plains of North America and wildebeest in East Africa. In these ecosystems, large herds of ungulates were a keystone feature that strongly influenced composition and structure. Plants are well adapted to herbivory in these grass-dominated ecosystems. However, large herds of ungulates are not a natural feature in all grasslands and savannas (e.g., the Intermountain and Palouse grasslands of the United States and the Brazilian cerrado). In these grasslands, rodents and insects are the dominant native herbivores.

The most widely distributed wild ungulates in North American grasslands and woodlands are pronghorn (*Antilocapra americana*), elk (*Cervus elaphus*), and deer (*Odocoileus* spp.). However, only bison comprised large herds within the Great Plains until they were decimated in the late nineteenth century by hunters. Bison also occurred in other North American grasslands, but not in large herds. Rodents and lagomorphs are also common grazers in North America. Population eruptions can result in years when the vegetation is heavily grazed by these animals in local areas, but within a few years disease, predators, competition, or other density-dependent factors reduce their numbers.

The common ungulates in South American grasslands and savannas include tapirs (*Tapirus* spp.), peccaries (*Catagonus*, *Dicotyles*, and *Tayassu* spp.), camelids (*Lama* spp.), and deer (*Odocoileus* and *Ozotoceros* spp.). Some of these are primarily forest or gallery forest (riparian) dwellers, but they also use savannas or grasslands. Only one native lagomorph (*Sylvilagus brasiliensis*) occurs in South America. The dominant vertebrate grazers in South American savannas are a diverse group of

Figure 3 An African woodland/savanna in South Africa. (Photo by Ron Shea.), with permission from Ron Shea.

rodents. The largest rodent, the capybara (*Hydrochoerus hydrochaeris*), is widely distributed, but prefers wetland savannas such as the Brazilian Pantanal. Capybara graze in herds as large as 1500 animals.

The African grasslands and savannas maintain the greatest species richness of wild ungulates of any rangeland ecosystem in the world (Figure 3). Rodents comprise a lower herbivore biomass than ungulates in most regions of Africa. The African ungulates consist of three taxonomic orders: Proboscidea (1 species; elephant); Perissodactyla (6 species; rhinoceros and zebras); and Artiodactyla, with five families. The families include Suidae (3 species; pigs), Hippopotamidae (2 species; hippopotamus), Tragulidae (1 species; water chevrotain), Giraffidae (2 species; giraffes), and Bovidae (79 species; buffalo and antelope). Although a few of the African ungulates are forest-specific species, most have distributions that include grasslands, savannas, and woodlands. Riverine and wetland locations with high rainfall in East Africa maintain populations of hippopotamus, waterbuck, and buffalo, whereas midheight grass regions with intermediate moisture support zebra, giraffe, and hartebeest. Native ungulates have been extirpated or driven to extinction in many regions of Africa. In the Fété Olé savanna of the Sahel, 11 species of native ungulates are now extinct.

Northern Asia has few native ungulates within its grassland/savanna ecosystems. Common ungulates include gazelle (*Procarpa* or *Gazella* spp.), wild horse (*Equus przewalskii*), and the Bactrian camel (*Camelus bactrianus*), and none of these form large herds. Rather, rodents are the primary vertebrate grazers within the northern Asian grasslands. They influence these ecosystems by creating local areas of high disturbance through digging and grazing. Voles, marmots, and ground squirrels often undergo population cycles that may result in the consumption of large amounts of vegetation when populations are high, thus reducing forage for local livestock herds. Such situations can exacerbate overgrazing since

livestock densities are not typically reduced in years of high rodent numbers. Southern Asia is more diverse in numbers of native ungulate species with the inclusion of several species of wild ass, gazelle, and antelope. Asian elephants and rhinoceros were also present, but are now endangered and extirpated from practically all of their former range.

In the Australian grasslands, large grazing animals are represented by marsupials (euros and kangaroos, *Macropus* spp.; wallabies, *Petrogale* spp.). The red kangaroo (*Macropus rufus*) grazes in the arid and semi-arid zones, whereas the antilopine kangaroo is restricted to tropical grasslands of the north. Introduced herbivores, such as the European rabbit (*Oryctolagus cuniculus*) and the Timor water buffalo (*Bubalus bubalis*), compete for herbage with native grazers in southern Australia. In Australia as throughout the world, the high productivity of grasslands and savannas has led to their widespread use by domestic cattle, sheep, and goats.

Temperate or Cold-Desert Shrublands and Semi-Deserts

Deserts or desert shrublands can be broadly classified into two different types—hot deserts of subtropical and tropical latitudes and cold deserts of temperate latitudes. Temperate deserts and semi-deserts occur at higher latitudes than hot deserts (between 30° and 50°), which allows for moisture from oceans to move into these regions by way of prevailing circulation patterns. Most of the temperate deserts and semi-deserts are characterized by sparse vegetation that is usually dominated by low shrubs and herbaceous plants. Total vascular plant cover rarely exceeds 50%, and biological soil crusts commonly occupy interspaces between vascular plants.

Cold deserts are characterized by cold winters and hot summers. Most occur in North and South America (Great Basin, Intermountain West, and Patagonia) and Eurasia (Kazakho-Dzungarian deserts and semi-deserts). In North America and western Eurasia, most of the annual precipitation

arrives as snow in the winter, while summers are dry. However, eastern Eurasia receives most of its moisture during the summer from frontal or cyclonal storms that move west from East Asia, while the winter remains dry. Patagonian semi-deserts receive low amounts of precipitation throughout the year, with strong winds exacerbating arid conditions during the summer from elevated evaporation.

The importance of native ungulates in cold deserts varies widely among these geographic regions. Large herds of ungulates, largely saiga antelope (*Saiga tatarica*), zheiran gazelle (*Gazella subgutturosa*), and wild ass (*Equus hemionus*), once roamed Eurasian ecosystems (until 100–200 years ago), but are now largely restricted to reserves. Wild sheep are common to both Northern Hemisphere ecosystems, with *Ovis ammon cyclocero* present in Afghanistan and Iran and *Ovis canadensis* in North America. Common native ungulates in North American cold deserts include pronghorn, deer, and elk. Feral horses and burros are now locally common in areas. Although bison were once found in this region, they never attained large numbers as found on the Great Plains and were largely absent by the time European exploration began. Only one native Patagonian ungulate exists, the guanaco (*Lama guanicoe*). Today domestic herbivores are predominate throughout all of these regions.

Hot Deserts

Hot deserts (or hot desert shrublands) are the most arid form of rangeland in the world. The hot deserts generally occur between latitudes of 15° and 30° N and S, the belt of the subtropical anticyclones that create near permanent high-pressure systems. Most hot deserts receive less than 120 mm of rain annually. The position within the high-pressure belts also results in a wide variation in the amount, location, and timing of rainfall. A wide spacing of drought- and heat-adapted shrubs is characteristic of hot desert shrubland vegetation. Perennial vascular plants normally cover less than 10% of the land area within hot deserts. Hot desert vegetation must be adapted to the uncertainty in the timing of adequate growing conditions that are characteristic of this ecosystem. The vascular plants persist in the variable and unpredictable growing conditions by using a host of adaptations to avoid dry seasons while quickly responding to moisture when it becomes available. Perennial plants often have persistent belowground organs that facilitate survival during the dry season. When moisture is available, some perennial plants can respond with a rapid production of adventitious roots and leaves. Many desert species (the Cactaceae, some Euphorbiaceae, and others) have photosynthetic stems that may allow growth during sporadic storm events without the cost of leaf production. Plant reproduction is limited to years with sufficient moisture. Ephemeral annuals survive in deserts by germinating and completing their life cycles during wet periods and then persisting in the soil as a dormant seed during dry periods. In locations where fog is the major source of water (coastal deserts of Chile, Peru, and Namibia), fog desert vegetation forms, with biological soil crust species often being the dominant ground cover.

Native ungulates are virtually missing from most hot deserts except along major rivers and wetlands. They may occupy

the fringes of the hot deserts and migrate into the deserts during favorable conditions. An example is the desert big-horn sheep in the North American Mojave Desert. Though populations are found in adjacent semi-deserts where greater food and water are available, use of the Mojave Desert by bighorn only occurs during wet periods. Australian marsupials follow a similar pattern, with most only using the arid desert areas during favorable times. A few wallabies are found in rocky arid areas, but never in large numbers.

Herbivores are found in low densities in the North African (Sahel and Sahara) and Middle Eastern deserts. Native ungulates of these deserts include gazelle, ibex, oryx, wild asses, and wild boar. The exception to a low density of ungulates in hot deserts is found in the Karoo and Kalahari Deserts of southern Africa. Here, springbok, gemsbok, and hartebeest disperse in small herds or treks during dry periods. Once moisture produces aboveground growth of grass, these animals congregate into larger herds. Populations of these animals 200 years ago were larger than those today. Although forage is scarce and unpredictable, domestic livestock (cattle, sheep, and goats) grazing remains common in hot deserts of the world.

Biological Impoverishment Associated with Livestock Grazing

Domesticated animals (livestock) have played prominent and largely beneficial roles in human society for thousands of years, providing food, fuel, fertilizer, transport, and clothing. Yet livestock have had a dramatic negative impact on global biodiversity. The influence of livestock on global biodiversity is of concern simply because cattle and all other ruminant livestock graze about one-third to one-half of the planet's total land area. Along with pigs and poultry, they eat feed and fodder raised on one-fourth of the cropland. Livestock grazing is the most ubiquitous human activity on Earth and occurs on more area than any other land use. The impacts of livestock are far-reaching and often not immediately apparent (Table 1). In many regions of the world, grazing has reduced the density and biomass of many plant and animal species, reduced biodiversity, aided in the spread of exotic species and disease, altered ecological succession and landscape heterogeneity, altered nutrient cycles and distribution, accelerated erosion, and decreased both the productivity and land use options for future generations.

Given the widespread degradation caused by livestock on the diversity and structure of native range-lands, one would assume that rangelands are the source of a large proportion of the feed utilized by the grazing animals on Earth. Yet it is estimated that three-quarters of the world's 3 billion domestic ruminants are raised in conjunction with farming and are fed crop residues, hay, and other forages such as alfalfa. Roughly 38% of the world's grain, especially corn, barley, sorghum, and oats, is fed to livestock. In the United States, livestock accounts for 70% of the domestic grain consumption; in contrast, India and sub-Saharan Africa provide about 2% of their cereal harvest to livestock. A 1983 U.S. Department of Agriculture report stated that ≈ 103 million ha of fertilized pastures and forage crops provided 84% of the U.S. livestock forage. The ≈ 312 –319 million ha of U.S. rangelands provided

Table 1 Some direct and indirect influences of domestic livestock on biological diversity

Desertification or degradation—the impoverishment of native plant and animal ecosystems
Deforestation/forest conversion to pasture
Contribution of greenhouse gases to the atmosphere—directly from methane emissions and carbon losses due to forest conversion
Conversion of native rangeland to cropland
Dispersal of exotic species and/or the creation of conditions suitable for their increase
Spread of disease to native herbivores
Geomorphic influences on stream channels (widening and incision) that disrupt floodplain/stream interactions
Water diversions for livestock forage production
Development of permanent water sources in areas where they traditionally did not occur
Erosion/sedimentation or fecal inputs into aquatic ecosystems
Influences on biogeochemical cycling
Control of wildlife species perceived as competitors or predators
Applications of herbicides and pesticides to control undesirable plants and insects
Altering natural fire regimes—elimination of fires in natural grasslands and shrublands or frequent introduction in pastures converted from tropical forests
Social causations—overpopulation, government incentives, culture, and customs

only 16% of the forage. Two-thirds of these rangelands are privately owned, and the rest are publicly owned. In 1984, permits issued by the U.S. Bureau of Land Management accounted for less than 4% of the forage consumed by the U.S. herds.

Rangelands of the world are important reservoirs of biological diversity as well as water, natural beauty, and other plant, animal, and mineral resources. For example, native rangelands provide essential habitat for a wide variety of wildlife and plant species. An estimated 84% of U.S. mammal species and 74% of bird species are associated with rangeland ecosystems (particularly using riparian zones within these semi-arid landscapes). Public rangelands in the United States are home to more than 3000 wildlife species, including about one-third of the nation's threatened or endangered species. Compared to forests, rangelands have received comparatively less attention with respect to environmental degradation in general, and losses in biodiversity in particular.

Because of the great differences in composition, soils, climate, and historical and current land uses among rangelands of the world, grazing effects will vary (see [Table 1](#)). Degradation occurs when the frequency, intensity, or season of use exceeds the biological thresholds for ecosystem persistence or recovery. Plant communities that evolved with large herds of ungulates may have adaptations that allow persistence with high levels of defoliation by domestic livestock. Conversely, those rangelands that evolved with low densities of large herbivores may be susceptible to alterations following the introduction of even low levels of domestic livestock impacts.

Unsustainable grazing and ranching practices result in the loss of forests, grasslands, shrublands, savannas, and the indigenous species that inhabit them. As the most pervasive land use, livestock grazing has had widespread and dramatic ecological impacts, including loss of native species, changes in species composition, soil deterioration, degradation of fish and wildlife habitat, and changes in ecosystem structure and function. The loss of biological diversity and productivity of range-lands due to overgrazing is a concern because it diminishes both human and ecological welfare. However, livestock influences on biodiversity are not limited to rangelands.

The range of environmental effects of livestock encompasses such varied land uses as conversion of tropical rain forest to pasture in the Amazon Basin, water pollution from manure associated with large livestock factory farms in Europe and the United States, and the desertification of semiarid rangelands in the African Sahel, western United States, and interior Australia.

Effects of Livestock on Terrestrial and Aquatic Ecosystems

[Figure 4](#) presents a simple model depicting how livestock influence biological diversity and ecosystem integrity. The direct or primary livestock influences are immediate and readily observable in the field. These direct influences include: (1) removal of vegetation through grazing; (2) the trampling of soils, vegetation, and biological soil crusts; (3) the redistribution of nutrients via forage removal, defecation, urination, gaseous loss, and animal gain; and (4) the dispersal of exotic plant species and pathogens. The cumulative effects of these four primary influences lead to a suite of physical and biotic responses or adjustments within the ecosystem or landscape. These are the secondary influences and they include alteration in disturbance regimes (fire cycles), accelerated erosion, altered hydrology (e.g., runoff, infiltration rates, and water-holding capacity), altered competitive relationships among organisms, and changes in plant and animal reproductive success and/or establishment patterns of plant seedlings. Tertiary influences are the long-term cumulative effects of domestic livestock on rangelands. These are the changes in structure, composition, and productivity of plant and animal communities that occur at community, ecosystem, and landscape scales. Tertiary influences are the overall declines in the biotic richness or diversity of affected aquatic and terrestrial areas as a result of long-term unsustainable grazing practices.

Alterations in aquatic and riparian ecosystems may include structural changes in stream channels, changes in water quality (temperature, chemistry, and sediments), and the loss of native aquatic biota. Tertiary influences are the manifestations of desertification and landscape degradation.

Figure 4 A conceptual model of the influences of livestock on ecosystem structure and function. Direct influences are those that are immediate and readily observable in the field. The synergistic effects of these influences lead to the secondary influences, the physical and biological adjustments in ecosystems. The tertiary influences are the long-term alterations in landscapes due to the introduction of livestock. Tertiary influences are the cumulative effects of the primary and secondary influences of livestock and are reflective of varying degrees of desertification or degradation. The degree of alteration would be affected by unique characteristics of the ecosystem (i.e., soils, topography, climate), as well as the intensity and frequency of livestock use.

Direct or Primary Influences

Forage removal by livestock can decrease the quality and quantity of forage for wild grazers as well as decrease nesting or hiding cover for other wildlife species. Vegetation removal by livestock can also reduce the protective litter layer, thus decreasing the quantity of carbon and nutrients incorporated into the soil as organic matter. Along streams, vegetation removal may affect stream shading as well as the amount of vegetation that enters into the stream. Vegetation inputs into streams are important because they are often the primary energy and nutrient source for headwater aquatic ecosystems in forests and rangelands.

The effects of herbage removal depend on a number of environmental, animal, and land management factors. The quantity of plant mass consumed and season, duration, and frequency of grazing are important determinants of how herbivory affects ecosystems. Overgrazing and degradation of ecosystems are a combination of excesses in all of these factors. The season of use refers to the phenological stage during which the plants are grazed. Typically, grazing when plants are dormant is less detrimental than grazing during active growth. Season of use may also influence the reproductive success of plants if flowers and seed heads are not allowed to form or are eaten. In addition, the degree of harm is dependent on the duration and amount of grazing. Declines in plant vigor will occur if grazing is of such duration or intensity that plants are not allowed to regrow and replenish carbon and nutrient reserves. For shrubs and trees, grazing more than the current year's growth will reduce the size of the plant and, depending on the plant's morphology, can result in the death of the plant. Finally, the frequency of grazing is an important determinant. Plants, other organisms, or soils in ecosystems in which grazing is interspersed with periods of rest have a greater opportunity for recovery than in ecosystems that are grazed continuously or annually (Box 1).

Trampling damage occurs via the mechanical compression and compaction of soils or the physical destruction of biological soil crusts or vegetation as animals move across the land. The break-up of soil crusts (both physical and biological) can increase soil loss via wind and water erosion. The susceptibility of soils to compaction is related to soil texture (sand, silt, and clay content), as well as the season of grazing. Clay soils are more susceptible to compaction than sandy soils and wet soils are more susceptible than drier soils. Soil compaction results in reductions in soil porosity, water-holding capacity, and rates of infiltration. All of these result in less water available for plant growth and more water lost via surface runoff.

Another direct impact of livestock is the influence on nutrient inputs and redistribution. The effects of herbivory on litter reduction, trampling, and soil compaction include direct influences on nutrient cycles. Trampling of biological soil crusts can reduce nitrogen inputs while increasing nitrogen losses via erosion. Urination and defecation are forms of nutrient redistribution. These inputs can enhance soil fertility, but can also have serious effects on water quality and aquatic organisms. Concentrated nutrient inputs can increase bacterial and protozoan pathogens, promote algal growth, and alter water chemistry—particularly the depletion of dissolved oxygen.

The final direct influence of livestock is the dispersal of undesirable exotic organisms (as well as native weeds). Seeds of exotic species may be transported on the fur or hooves of animals or deposited in the feces. As livestock move through an area, they may deposit exotic plant seeds while simultaneously preparing a seedbed via trampling. A grazing preference for desirable native species may further improve the competitive advantage of the less desired weeds, thus increasing their probability of establishment and dominance. Animals do not graze indiscriminately. Different animals have

Box 1 Riparian zones: Hot spots of biodiversity on rangelands

Riparian zones are the unique environments adjacent to rivers and streams and comprise assemblages of plant and animal communities whose presence can be either directly or indirectly attributed to factors that are stream-induced or stream-related (Kauffman and Krueger, 1984). Functionally, they are three-dimensional zones of direct interaction between terrestrial and aquatic ecosystems. Boundaries of riparian zones extend outward to the limits of flooding and upward into the canopy of streamside vegetation (Gregory *et al.*, 1991). These zones perform a variety of ecosystem functions, including influences on water quality, flood attenuation, and provision of valuable fish and wildlife habitats.

Riparian areas are hot spots of biodiversity. This is particularly true in arid and semiarid environments, where riparian zones may be the only tree-dominated ecosystem in the landscape. The presence of water, increased productivity, favorable microclimate, and unique disturbance (flooding) regimes combine to create a disproportionately higher biological diversity than the surrounding uplands. In the Intermountain West and Great Basin of the United States, about 85% of the wildlife species are dependent on riparian zones for all or part of their life cycles. In these same riparian zones, well over 100 plant species commonly can be found on a single gravel bar (<50 m in length along the streambank).

Livestock grazing is among the most significant land uses affecting the structure and productivity of riparian zones. Because of the high plant productivity, close proximity to water, favorable microclimate, and level ground, these areas are preferred habitat for livestock, and overgrazing commonly occurs. Grazing changes the composition and structure of the riparian zones, which lead to dramatic effects on the large numbers of wildlife that use the areas for feeding, breeding, or hiding cover. Of particular importance are the effects of livestock grazing on streamside forests of cottonwood, aspen, and willows. Long-term overgrazing can eliminate the woody vegetation that provides essential breeding bird habitat. In addition, trampling in riparian zones decreases infiltration and breaks down streambanks, resulting in channel incision or widening. These influences on streambank structure sever the linkages between the riparian and aquatic zones through the elimination of overbank flooding. The removal or loss of riparian vegetation results in the decline of organic inputs into the stream and the loss of overstory vegetation shade, which can dramatically affect the aquatic biota, such as salmon and trout.

Because of the high level of biodiversity and other ecosystem values of riparian zones, particularly in semiarid and arid environments, their restoration yields many positive benefits. Riparian zones are naturally an environment with frequent disturbances (floods), and because of this, the adapted biota often exhibit considerable resilience following the cessation of land uses that cause degradation or that prevent recovery. In rangelands, this most often includes abusive grazing practices. Thus, the cessation of overgrazing is the first important step in riparian restoration and should be implemented prior to determining if other active restoration measures need to be taken. For lasting riparian restoration, a larger effort should be aimed at the recovery of the entire watershed (Kauffman *et al.*, 1997).

preferences and select some plant species over others. This will confer a selective advantage on less palatable species over those preferred by livestock. Often exotic species are less palatable and more grazing tolerant than native species. Livestock grazing in rangelands where native species are not well adapted to large herbivores will confer a selective advantage to exotic plant species.

Livestock also spread exotic diseases to native herbivores. Numerous herds of bighorn sheep in the United States have been eliminated following disease transmission from domestic sheep.

Indirect Effects: Secondary and Tertiary Influences

The direct or primary influences of livestock elicit a number of feedback responses that affect additional species, functions, and processes. The outcomes of these far-reaching effects are described as secondary influences and include changes in landscape disturbance cycles (e.g., fire regimes), accelerated rates of erosion, alterations in hydrology and plant available water, and alterations in successional patterns due to changes in competition and reproduction of both the native and exotic species (see Figure 4).

The cumulative impacts of livestock grazing are apparent in many desertified or degraded ecosystems throughout the world. The tertiary influences of livestock overgrazing on ecosystems are the characteristic endpoint of desertification or land degradation (Figure 4). The tertiary effects include dramatic alterations to the biotic structure, composition, and

productivity of ecosystems. These are closely linked to simultaneous degradation of hydrological and soil properties. Declines in the cover of native perennial plants and biological soil crusts and concomitant increases in bare ground, unpalatable shrubs, or noxious weeds and annuals are examples of the long-term degradation of ecosystems. Tertiary effects of livestock are often difficult to separate from other significant influences on ecosystems. Degraded landscapes are often the cumulative result of inappropriate livestock management in concert with other poor land management practices, including logging, road building, inappropriate agronomy, fuel-wood harvesting, mining, water diversions, and over-harvesting of plant and/or animal resources (i.e., hunting, poaching).

Livestock Grazing and the Desertification of Native Rangelands

Desertification of rangelands has had strong negative effects on Earth's biodiversity and the continued rate of desertification represents a major global threat. Desertification is manifested in a combination of declines in native species diversity, ecosystem productivity, loss of topsoil, changes in nutrient cycles, and alterations in hydrology and microclimate. For example, Flather *et al.* (1994) reported that 40% of all U.S. federally listed Threatened and Endangered (T&E) species were associated with rangelands. More T&E plant species occur on rangelands in the United States than any

other land cover type. Trends in biodiversity loss are likely similar in other rangelands of the world. This is particularly true for large native herbivores, which are now largely restricted to small preserves or parks. Nearly all of Earth's rangelands have been degraded by human activities, including livestock grazing, the introduction of exotic species, fuelwood harvesting, alteration of natural fire cycles, wildlife depredation, and conversion to cropland or urbanization.

Estimates by the United Nations Environmental Programme (UNEP, 1990) indicated that 73% of the world's 3.3 billion ha of dry land is at least moderately desertified, having lost more than 25% of its productive capacity. It has been estimated that $\approx 84\%$ of the world's rangelands are at least moderately desertified (i.e., conditions in which plant productivity has declined by $\geq 25\%$; or indications that accelerated wind or water erosion has occurred due to land use; or soil salinity has reduced crop yields 10–50%). Of the 3.1 billion ha of rangeland in the world, Mabbutt (1984) estimated that as many as 1.3 billion ha are severely degraded (i.e., productivity loss exceeds 50%).

The UNEP study on soil degradation reported that over the past 45 years about 11% (1.2 billion ha) of Earth's vegetated soils have become degraded to the point that their original biotic functions were damaged; reclamation would be costly or in some cases impossible. Most of these degraded soils are suffering from "moderate" degradation, that is, productivity is greatly reduced but can still be used for agriculture. The soil's original biotic functions (its capacity to process nutrients into a form usable by plants) have been partially destroyed and only with major improvements can productivity be restored. A smaller proportion ($\approx 3\%$ of Earth's surface) showed severe degradation, where original biotic functions are largely destroyed and may be reclaimable only with major financial and technical assistance. Nine million hectares of land were classified as extremely degraded, that is, unreclaimable and beyond restoration. On this land the original biotic functions are fully destroyed. At continental scales, land areas with soil degradation classified as moderate to severe ranged from 4.4% in North America, to 14.4% in Africa, to 24.1% in Central America and Mexico.

Throughout the world, accelerated wind and water erosion is the process that causes the majority of soil degradation, and overgrazing is the most ubiquitous cause of the acceleration in the erosion process. Globally 35% of the soil degradation that has occurred since 1945 was attributed to overgrazing (UNEP, 1990). Thus overgrazing is the most pervasive cause of soil degradation, affecting 679 million ha. In Africa and North America, grazing was the principal cause for 49 and 30% of the soil degradation, respectively. Soil erosion resulting from the decrease in plant cover and trampling may require thousands of years for recovery, particularly in semiarid and arid ecosystems.

Perhaps the largest data set showing trends in the ecological condition and biological impoverishment of rangelands at large scales (country or continental scales) are those of public lands in the western United States. Determining the pristine state of rangelands is difficult, and current approaches are being challenged as to their usefulness for truly ascertaining ecological condition. This is because few areas of undisturbed or pristine rangeland exist (i.e., areas with no history

of livestock grazing), unlike the case with old growth or primary forest (i.e., never deforested). In addition, comparison of the degree of departure from a single hypothetical climax composition is specious at best. Keeping in mind these uncertainties associated with ecological interpretations of rangeland condition, only about 4% of nonarctic rangeland in the United States is considered to be in excellent condition (i.e., covered with native vegetation and suffering no loss in productivity). Most U.S. rangeland is in fair or good condition (i.e., slight to moderate degrees of degradation), but a significant portion (15%) is categorized as poor or severely degraded. In 1990, the U.S. Bureau of Land Management reported that only 33% of its holdings were in good or excellent condition.

Range trends, whether the rangelands are improving, degrading, or static, are a measure of how well rangelands are being managed. The results vary depending on the parameters examined. The U.S. land-managing agencies suggest that about 86% of rangelands are either improving or static (i.e., exhibit no discernable trend), and that 14% are degrading. Yet portions considered static or stable may be in such a degraded ecological state that further decline would be difficult to discern. For example, many western rangelands are completely dominated by exotic annuals or weeds, and others have experienced extensive shrub encroachments during the latter half of the twentieth century. These patterns make it difficult to interpret landscape-scale changes in ecological condition.

Though many scientists believe that many U.S. rangelands are currently in the best ecological condition of the last 60 years, others point out that more than 50% of the rangelands contain less than half of their potential natural plant composition after more than 50 years of "modern range management" (i.e., directed toward recovery and sustained use). Because of the loss of soil and native species, coupled with ongoing invasions of exotic species, many suggest that desertified North American rangelands will not likely regain their former diversity in time frames of less than a century. Research and innovative approaches for the restoration of biological diversity of rangelands are needed.

Conversion of Tropical Forests to Livestock Pasture

Livestock impacts are not limited to Earth's rangelands. Rain forests are among the most biologically diverse ecosystems in the world. Tropical forests cover about 720 million ha and contain 40–90% of the world's species. The dramatic rate of conversion of tropical forests to cattle pastures is one of the most deleterious environmental impacts on global biodiversity in the latter half of the twentieth century. Conversion of tropical forest to pasture not only results in the extirpation of native rain forest plants and animals, but also alters the microclimate, hydrology, and fire cycles, and is a significant source of greenhouse gases (Box 2).

Most of the deforestation in the tropical rain forests, moist forests, and dry forests of Latin America is for conversion to cattle pasture. In addition to soil, climatic, and vegetative characteristics, socioeconomic status of the landowner is a determinant of the patterns of land use. For example, on large ranches in the Brazilian Amazon, tropical forests are converted

Box 2 Biological soil crusts: Their role and susceptibility in rangeland ecosystems

Biological or microphytic soil crusts consist of a combination of nonvascular plants (also known as cryptogams; these include cyanobacteria, mosses, lichens, liverworts, and green algae). Biological soil crusts serve a number of ecosystem functions that make them an important component of the biological diversity of many of the semiarid and arid environments of the world. These soil crusts exist in nearly all ecosystems where vascular plant material (live or dead) covers less than 100% of the ground surface; they occupy the interspaces between vascular plants. Spatial coverage within some ecosystems may be greater than that of vascular plants, ranging from 10 to 100% coverage in some undisturbed temperate and arctic ecosystems. Biological soil crusts are adapted to extreme environmental conditions of extended drought and extreme high and low temperatures. These species are metabolically active only after hydration. Some are able to hydrate under conditions of saturated air, such as fog, dew point, or high vapor pressure; others require liquid water.

The functional role of biological soil crusts in semiarid and arid ecosystems is multifaceted. Some species are involved in the breakdown of humus and in the release of nutrients. However, a more significant role in some ecosystems may be their direct contribution of increasing nitrogen availability to other plants and organisms within the ecosystem through biological nitrogen fixation. Nitrogen is often an important limiting factor for ecosystem productivity. Biological soil crusts (cyanobacteria and cyanolichens) can be important sources of nitrogen for many semiarid ecosystems, such as the North American Great Basin and Colorado Plateau. Fixed nitrogen is immediately released by these organisms into the surrounding soils; however, the amount taken up by vascular plants has not been widely studied.

Biological soil crusts can diminish the rate of wind and water erosion from rangelands. Soil stability is enhanced by these soil crusts through the formation of exudates of polysaccharides that bind soil particles into aggregates. They also protect the soil from raindrop erosion (the dislodging of soil particles by individual raindrops, also known as splash erosion) by absorbing the kinetic energy of raindrops. The potential to diminish soil erosion varies with biological crust composition, increasing from algal, to lichen, to moss-covered crusts. Crusts create a surface roughness that slows the surface runoff of water and may trap soil particles arriving via wind deposition. The phototropic nature of the crust species is an adaptation that contributes to their upward growth and soil entrapment when soil buries the crusts. They are important contributors to dune stability when dunes consist of sufficient amounts of fine soil particles (silts and clays).

Complex direct and indirect mutualistic relationships exist between biological soil crust and vascular plants. In addition to nitrogen fixation and soil stability, the presence of soil crusts is positively correlated with floristic diversity in several ecosystems around the world. This positive correlation may be related to the increased seedling establishment and survival of vascular plants when grown in association with biological soil crusts. The surface variation that crust species provide may also contribute to greater variation in suitable sites for successful seedling germination and establishment.

Throughout the rangelands of the world, the introduction of large numbers of domestic ungulates has damaged biological soil crusts via herbivory and trampling. Herbivory by ungulates is generally restricted to locations where domestic reindeer have overgrazed lichen-dominated winter habitat in arctic tundra ecosystems. Globally, the most prevalent ungulate impacts are related to trampling, which breaks the dry, brittle lichens into small pieces that are then blown from the site. In many rangelands, intense grazing by livestock around watering places results in the elimination of lichens near the water; as distance from water increases, livestock impacts on lichen abundance decrease. Biological soil crusts growing on soils with low aggregate stability (i.e., sandy soils) are more susceptible to trampling damage during dry periods. The disruption of the dry soil surface breaks the bonds between the biological soil crust and the soil. Both the soil particles and the crust species are then susceptible to wind and water erosion.

Following disturbance or loss, biological crust recovery time depends on the severity of the disturbance and the environmental characteristics of the ecosystem. Primary recovery begins with cyanobacteria within one year after disturbance. Belnap (1993) estimated that some ecosystems in the U.S. Southwest may require 30–40 years for the replacement of sheath material in the soil, 45–85 years for lichen diversity to recover, and over 250 years for moss cover to return if left undisturbed. Recovery of crust species is more rapid in locations with higher effective precipitation and finer-textured soils, and if inoculating material is present. Clearly, ecosystems in which biological soil crusts are a major component need appropriate grazing management or protection to maintain or restore biodiversity and to prevent degradation, erosion, and desertification.

directly to cattle pasture. In contrast, small-scale subsistence farmers may use the land for one or two shifting cultivation cycles before ultimately converting to cattle pasture.

Slashing and burning tropical forest for cattle production converts some of the most structurally and biologically diverse ecosystems on Earth to simple pastures dominated by exotic grasses (Figure 5). Rain forests frequently have over 100 canopy tree species per hectare and millions of highly interdependent organisms living within the forest and soil. In contrast, the only trees, if any, in pastures are cultivated fruit and nut trees or highly invasive second-growth trees. Rather than the diverse array of birds, mammals, insects, reptiles, amphibians, and other native tropical fauna, the pastures are dominated by the cattle and the few other animals that thrive in human-modified environments.

Deforestation affects biological diversity in three ways: (1) destruction of habitat; (2) fragmentation of formerly contiguous forest habitat; and (3) edge effects within the forest that is immediately adjacent to pastures. In fragments and edge forests, the microclimate is altered such that temperatures and wind speeds are higher, and relative humidity is lower.

Higher wind speeds and drier conditions result in increased tree losses due to windthrow and maybe increased water stress. The drier conditions, in concert with increased quantities of dead wood, increase the susceptibility of fragmented and edge forests to wildfires. Ignition sources for wildfire are widespread in a tropical landscape mosaic of fragmented forest and pastures because fire is frequently used to maintain the pastures. Because native flora and fauna are poorly adapted to fires in tropical rain forests, even light fires result in high rates of mortality. Low-intensity fires that spread from cattle pastures to adjacent edge forest have been found to completely kill the overstory canopy, while only $\approx 40\%$ of the species had the capacity to sprout after burning (Kauffman, 1991).

Data from the Brazilian space agency (INPE) and the U.S. Space Agency (NASA), as well as that from other Brazilian and U.S. scientists, indicate that the Amazon Basin is experiencing the world's highest absolute rate of forest destruction. The rate of deforestation averaged $15,000 \text{ km}^2 \text{ yr}^{-1}$ from 1978 to 1988, while the rate of habitat degradation (i.e., the sum of cleared and fragmented lands) was $38,000 \text{ km}^2 \text{ yr}^{-1}$. The rate of deforestation has accelerated in recent years from about

Figure 5 Tropical rain forests are among the most biologically diverse ecosystems on Earth. The principal cause of deforestation in the Neotropics (and elsewhere) is for cattle pasture conversion. In this photo, the biologically diverse rain forest has been replaced by a pasture dominated by a few exotic grasses and invasive plants, with permission from Boone Kauffman.

11,000 km² yr⁻¹ in 1991 to just over 20,000 km² yr⁻¹ from 1995 to 1997. At the rates experienced in the late 1990s, 5479 ha of forest are lost every day; this is equivalent to about 3.8 ha destroyed every minute.

It is difficult to determine the total area of tropical rain forest that has been converted to cattle pasture. [Fearnside \(1993\)](#) reported that by 1991 the area of forest cleared in the Amazon Basin had reached 426,000 km². This estimate did not take into account forest areas affected by fragmentation and edge effects. Cumulatively, areas in which biodiversity has been affected by forest clearing (primarily for cattle pasture) may be over twice that of deforestation alone ([Skole and Tucker, 1993](#)). Because about 13% of the region has now been deforested (INPE, 1996, 1998), the total area affected by deforestation and fragmentation could comprise a third of the entire Amazon Basin.

Rain forests tend to receive the most attention, but tropical dry forests have been deforested to an even greater degree. These are also the most abundant type of tropical forest. Few areas of intact (i.e., uncut or primary) tropical dry forest still exist in Latin America today (e.g., the Brazilian caatinga and tropical deciduous forests of Central America and Mexico).

Although scientists and economists have questioned both the sustainability and economic viability of cattle pastures in areas of former tropical forest, the deleterious consequences to biological diversity are evident. If cattle pasture production is neither sustainable nor economically viable, then why are rates of deforestation so high? Contrary to popular belief, deforestation in the Americas has not been a response to international demands for beef nor a response to increasing human populations (hoof-and-mouth disease is prevalent in Brazilian cattle, which precludes importation into the United States, and the Amazon Basin supports only $\approx 5\%$ of all cattle production in Brazil). Deforestation largely occurs because it

is a way to obtain title to the land, or to profit from land speculation, government financial incentives, and subsidies. In addition, labor costs on ranches are quite low compared to intensive agriculture or agroforestry systems. The environmental limitations in many tropical landscapes, coupled with governmental and social forces, combine to promote a land use that produces little food and little direct monetary return, but tremendous environmental degradation ([Hecht, 1983](#)).

Livestock Grazing and the Greenhouse Effect

Livestock production and related land uses are significant sources of many greenhouse gases. In addition, changes in climate due to the greenhouse effect are predicted to have strong feedbacks on the environments that provide feed and water for livestock. Among the most significant influences of the livestock industry in relation to the greenhouse effect is slash burning, which occurs during the conversion of tropical rain forest to pasture. When slashed tropical rain forest burns, as much as one-half of the aboveground carbon (76–112 Mg ha⁻¹) may be released as CO₂, CO, and other radiatively active gases. As much as 800–1600 kg nitrogen ha⁻¹ are also released by burning forest ([Guild et al., 1998](#)). When tropical dry forest is slashed and burned, the proportion of biomass consumed is even greater—as much as 95% of the aboveground carbon pool may be released as greenhouse gases during slash fires. The burning of the African savannas, most often initiated by herders for forage enhancement, is another important source of CO₂. Savanna fires contribute as much as 16% of the total annual CO₂ arising from agricultural sources. However, much of this will be absorbed the following year by regrowing grasses. The same is not true for forest that is converted to pasture; the biomass of pasture grasses will be about 5% of the forests that it replaced.

Methane is a powerful greenhouse gas with a radiative absorption capacity that is 21 times that of CO₂. The global increase in methane results from human activities such as livestock production, manure management, rice production, landfills, and the production and use of oil, gas, and coal. Livestock and manure management contribute about 16% of the total annual methane production (about 87 million Mg out of 550 million Mg produced each year; de Haan *et al.*, 1996). Methane emissions from ruminants (cattle, sheep, and goats) result from their capacity to utilize large amounts of fibrous grasses. Low productivity and poor feed quality are characteristic for most land-based ruminant production systems in arid regions. Poor feed quality also typifies pastures in the tropics and subtropics. In these scenarios, emissions per animal are higher than in scenarios where animals are on higher-quality feeds. With the conversion of tropical forest to cattle pasture, not only are large carbon sinks shifted to significant global atmospheric carbon sources, but the resulting land use becomes a significant global methane source.

Other Factors

Conversion of Native Rangelands to Croplands or Pasture

In addition to the effects previously mentioned, there are many other livestock-related land use activities and industries that affect global biological diversity (see Table 1). Grazing on native grasslands and shrublands supports a dwindling share of the livestock forage supply of the world. As intensive livestock production has expanded and the importance of grazing native rangeland has declined, there have been large conversions of rangelands to seemingly more lucrative land uses. The highly diverse Brazilian cerrado, a mosaic of savanna, grasslands, and open evergreen woodlands, covers about 2 million km² in Brazil. The cerrado is undergoing a rapid conversion from species-rich savanna/woodland to planted pastures, soybeans, and other annual crops. This region has experienced more land cover change than the Amazon forests (i.e., about 600,000 km² of the cerrado had been cleared as of 1991, compared to about 400,000 km² for the Brazilian Amazon; Klink *et al.*, 1994).

Many rangelands of the U.S. Southwest and southern Great Plains were plowed into croplands when government subsidies made it cost-effective to utilize groundwater for irrigation (i.e., the Ogallala aquifer). Often, these water sources were rapidly depleted and groundwater became prohibitively costly to pump. This resulted in the abandonment of lands that are now in a desertified state—a depauperate cover of native vegetation coupled with high rates of soil erosion.

Exotic Species and Pathogens

Invasions of exotic species are among the greatest threats to global biodiversity and livestock play significant direct and indirect roles in facilitating their establishment. Livestock influence exotic plant distribution through seed dispersal in fur and dung. Establishment of exotics is enhanced via creation of seedbeds through trampling and forage removal. In those regions where large herbivores were not a strong selective pressure on the native flora (i.e., much of the Pacific Northwest, Intermountain West, and California, in the United States),

exotic annuals now dominate areas formerly dominated by perennial bunchgrasses. Indirectly, the livestock industries also facilitated introductions and spread of exotic plant species through cropland plantings (fodder and feed grains) that contained weed seeds.

In contrast to unanticipated shifts of native ecosystems to exotic species dominance, many native rangelands and forests have been converted to exotic grass dominance through purposeful seeding. The goals of these so-called “range improvements” were to increase forage for livestock, decrease soil erosion, and provide a desired alternative to weeds. However, there was scant consideration for influences on biological diversity. For example, in the United States millions of hectares formerly occupied by shrub/bunchgrass ecosystems have been seeded with grasses of exotic origin (e.g., crested wheatgrass, *Agropyron cristatum*, and Lehmann lovegrass, *Eragrostis lehmanniana*).

Livestock, Water Developments, and Aquatic Ecosystems

Livestock and related management activities have strong effects on the biodiversity of aquatic ecosystems. These not only include direct effects such as consumption of streamside or wetland vegetation, trampling of streambanks, and fecal inputs, but also indirect effects such as irrigation withdrawals, water developments, and wetland draining. These activities can alter aquatic diversity through degradation of aquatic habitats as well as water quality (temperature, chemistry, and microbial composition). Numerous studies have documented accelerated streambank erosion and losses of streambank structure due to livestock grazing. The changes and the accrual of sediment in the channel degrade spawning and reproductive habitats for fishes and aquatic insects. Overgrazing results in the simplification of stream channels, which may include loss of channel sinuosity, increases in channel widths, increased channel incision, and decreases in deep pools. Incised and simplified channels result in the elimination of important linkages between the floodplain and stream channel that positively influence biodiversity.

Water diversions for pasture or forage crop irrigation are a widespread influence on the biodiversity of rivers streams and their associated riparian zones. Diversions range from the dewatering of small streams for the irrigation of a single pasture or farm field to huge dams that span major rivers. Regardless of the scale, when water is diverted or dammed, the natural hydroperiod of the river or stream is altered (i.e., changes in the timing and magnitude of peak and low flows throughout the year). This can have dramatic influences on channel-forming processes and riparian community development. Because many aquatic and riparian organisms are adapted to cycles of floods and flood effects, these hydrological alterations can completely alter their environment, leading to species losses. Throughout the western United States, livestock-related agriculture is a dominant user of irrigation water stored in federally-constructed dams. Significant detrimental effects on native fishes, as well as on biologically diverse riparian plant and animal communities, occur both upstream and downstream of the dams or diversions.

Land rehabilitation and forage enhancement efforts have been attempted throughout degraded rangelands of the world. However, these have often had disappointing results. Because

of misinterpretations of ecosystem needs or ignorance of ecological consequences, rehabilitation efforts have sometimes exacerbated the deterioration and degradation that they were intended to reverse. A striking example is the establishment of permanent water sources in dry season grazing areas in Africa (similar developments have also been implemented in the U.S. West). Water sources were developed in areas so distant from surface water that they were not traditionally used by livestock during the dry seasons. Following developments such as the drilling of wells or construction of small catchment basins, lands around these African water sources were often severely overgrazed and trampled. In addition to losses in biodiversity, these water sources have fostered the growth of herds beyond the carrying capacity of the land, resulting in range deterioration and livestock deaths during droughts. During droughts, livestock did not die from lack of water but from starvation. The ultimate consequences include degradation of the native ecosystem coupled with increased human suffering and hardship.

Water pollution is a common problem associated with intensive livestock production in relatively confined spaces. Manure is a valuable organic fertilizer and soil builder in modest amounts, but it is a dangerous environmental hazard when waste production exceeds the absorptive capacity of land and water. In fecal-polluted waterways, pathogens detrimental to both the native biota and humans are present. In addition, increased nitrogen and phosphorus concentrations can result in the eutrophication of waterways, in which algae blooms rapidly consume oxygen to the point where fish kills occur.

Biogeochemical Cycling

Livestock grazing can affect nutrient cycling in numerous ways. The most obvious would arise from the dramatic effects associated with accelerated erosion, trampling of soils, and the replacement of perennial plants (and often biological soil crusts) with annuals or shrubs and bare ground. The direct consumption of vegetation changes the patterns and distribution of litter, which affects decomposition and nutrient cycling. Consumption of herbage resulting in less litter also increases the proportion of bare ground, thereby increasing susceptibility to erosion. Accelerated erosion results in the loss of nutrients, soil organic matter, and the capacity of the soil to store water and retain nutrients. In riparian zones, diminished litterfall can also affect the aquatic biota. For many headwater streams, the nutrients and energy that drive in-stream aquatic ecosystems are derived from terrestrial inputs. It is particularly deleterious to aquatic ecosystems when long-term grazing results in the elimination of shrub and tree overstories in streamside environments.

The synergistic effects of forage removal and trampling damage by livestock have been described in Oregon riparian meadows that were grazed for over a century. Grazed meadows had lower rates of nitrogen mineralization and lower soil organic matter than areas where grazing had been halted for 9–12 years. These indicators of decreased productivity were associated with dramatically lower water infiltration rates, higher soil bulk density, lower levels of residual litter, and lower root biomass in the grazed sites.

Desertification often results in the alteration of natural desert grasslands and savannas into shrublands with bare soil

in the intershrub spaces. Under these scenarios, nutrient and water resources become concentrated under shrubs. Livestock grazing can also concentrate nutrients in areas where livestock may congregate through the concentration of urine and feces (i.e., resting places, water holes, or streamsides).

Attempts to Control Undesirable Species

Other activities associated with livestock management that affect biodiversity include predator control (e.g., eliminating carnivores via trapping, poisoning, or shooting) and other forms of wildlife control for species that are perceived as competitors with the livestock industry. These activities, called “animal damage control,” are often carried out without consideration of their effects on biodiversity, ecological processes, or ecosystem functions. Techniques of animal damage control are often not specific to the “target species” and other “non-target” species can be eliminated as well. Poison bait traps and many pesticides often kill nontarget animals (and insects). The black-footed ferret (*Mustela nigripes*) was almost driven to extinction because of the decline of the prairie dog (*Cynomys* spp.), its major prey. Prairie dog populations have precipitously fallen due to habitat loss by agricultural development and from purposeful elimination because they eat the same forage as livestock. Many large carnivores have been eliminated in regions because of their real or perceived threats to livestock. The livestock industry interest groups provide the most vehement opposition to the reintroductions of large carnivores to extirpated ranges (e.g., wolves to Yellowstone National Park).

As with predator control, the use of petrochemicals (herbicides and pesticides) to control unwanted species of plants and insects has sometimes resulted in undesirable effects on non target species. In animal, plant, and insect control programs, scant attention has been paid to the functional role that these organisms may play in ecosystems and possible feedback responses to their removal. In addition, questions regarding the underlying reasons for the increase in pest or weed damage frequently were not asked or left unanswered. In the western United States, practices such as mechanical and chemical removal of shrubs and trees were implemented for the benefit of increased cattle forage, but at the expense of other human and ecological values. For example, widespread rangeland herbicide applications eliminated traditional food and medicinal plants used by indigenous peoples on many western U.S. rangelands. This is because herbicides applied to control unwanted plant species also kill a suite of other native broad-leaved species. Species with limited capacities for reinvasion may be locally extirpated from sites after a single herbicide application. Similarly, insecticides may lack selectivity, such that a suite of species performing a multitude of ecosystem functions are eliminated. Many of these chemicals act as environmental estrogens and their elevated concentrations within secondary consumers (predators and scavengers) have resulted in reproductive and physiological maladies.

Altering Fire Regimes

In many grasslands and savannas of the world, fire is a dominant disturbance feature of the landscape. The high productivity of flammable grasses, climatic conditions with

long dry periods, and a prevalent ignition source (lightning or humans) result in the frequent occurrence of fires. Fires in grasslands and savannas are important in cycling nutrients and in influencing biotic structure and composition. Both the flora and fauna of grasslands and savannas are adapted to, and often dependent on, fire for their continued existence. Altering the fire regime can lead to a vastly different structure and composition. Livestock alter fire regimes by removing the fuels (i.e., the grasses) that carry the fire in rangelands and savannas. For example, throughout the U.S. West, livestock grazing has resulted in the diminution of fires in rangelands with a concomitant increase in shrub species that are not as fire-adapted. Increases in the abundance of juniper (*Juniperus* spp.) and mesquite (*Prosopis* spp.), as well as declines in aspen (*Populus tremuloides*), are related to the synergism of livestock and the decline of fire occurrence. Long-term changes in ecosystem structure due to grazing and fire suppression have resulted in a scenario in which simple livestock removal would not completely remedy the ecosystem decline; vegetation manipulations coupled with the reintroduction of fire would also be necessary components of ecological restoration.

Conclusions: Human Institutions and Livestock-Caused Degradation

Livestock create an array of environmental problems, not because cows, sheep, goats, and other grazers are hazards in themselves, but because human institutions have forced animal farming out of alignment with the ecosystems in which they are practiced. The root causes of land degradation, including deforestation and desertification, lay not in the animals, but in the social and political institutions and population pressures placed upon the environment. Socio-political causations must be addressed if degradation of biodiversity by livestock is to be halted and ecosystems restored.

In many countries there persists government-based subsidies and economic incentives that result in the expansion of livestock production that accelerates environmental degradation. Government policies on pricing, taxing, and land titling incentives affect resource use by influencing decisions about type of use, inputs, technology adoption, and investments in development. Policies have misguided livestock development through the subsidized pricing of inputs and products that induced the non-sustainable use and degradation of natural resources. Resources have been priced too low to reflect their true environmental costs, thus passing the debt of environmental degradation along to future generations. In the United States, subsidized grazing on public lands and federal dams that provide water for irrigated pasture and fodder production are prominent examples. In the Brazilian Amazon, land speculation, titling procedures, and government financial incentives have been the main reasons for the conversion of tropical rain forests into cattle pastures. In many less-developed countries, strong human population growth is fueling demand for livestock products while at the same time limiting the traditional sources for livestock production. Increases in per capita income and urbanization are raising the demand for livestock products. The growing social inequalities among

the rich and the poor result in different motivations for degradation: the greed of the rich and the desperation of the poor.

Desertification is the result of inappropriate land use activities, including overgrazing, overcultivation, salinization due to irrigation practices, and deforestation. Although differences exist among different rangelands, cultures, and countries of the developing world, the underlying forces of degradation include population densities that are greater than the land can sustain and, more fundamentally, social and economic inequities that push people into marginal environments and vulnerable livelihoods. Particularly important in the developing world is the inequitable distribution of land among the rich and poor. When a disproportionate share of the land is kept in the hands of a few, the ability of the impoverished majority to sustainably manage the marginal lands that they control is severely compromised.

The first step in the ecological restoration of degraded rangelands is the cessation of those activities that are causing degradation or preventing recovery (Kauffman *et al.*, 1997). Changing the social and institutional incentives that result in the degradation of ecosystems may be more difficult to achieve than the biological and physical aspects of ecosystem restoration. It must be recognized that sustained productivity and livelihoods will most likely occur when lands are managed in a manner that closely approximates their evolutionary development and where ecosystem processes are allowed to occur with minimal disruptions or alterations. In rangelands, management that mimics the natural grazing patterns of large wild herbivores may be the most sustainable and successful in maintaining biological diversity. Practices that maintain functional ecosystems rather than attempt to maximize short-term meat production are an integral feature of sustained land management. Similarly, if functional features and biodiversity are to be maintained in forests, the utilization of standing rain forest should be encouraged rather than replacing them with cattle pastures.

Glossary

Fishing effort Level of fishing activity quantified in terms of the number and power of vessels and duration of fishing.

Maximum sustainable yield Maximum average level of catch that can be removed from fish population over a very long time period.

Mesh size Size of the holes in a fishing net.

Recruits Young fish that are first caught by a fishery.

Stock recruitment relationship Relationship between the adult breeding stock and the number of recruits produced by that stock.

Total allowable catch Level of permitted catch established by fishery regulations.

History

Fishing as a commercial activity has been conducted since the very earliest of times. Early records indicate that it was occurring in both Egyptian and Indian societies as long ago as 5000 BC, and fisheries in the Mediterranean were already significant as long ago as 1000 BC.

Since the early years, fishing has increased largely as a result of the changes that have occurred in the human population and its activities. In **Figure 1(a)**, the estimates for world population from 1800 are shown. This shows an increase from around 1 billion in 1800 to 7 billion at present. The major increase in population has occurred in the past 100 years or so, and particularly since 1950 the rate of increase has been very high.

In **Figure 1(b)**, estimates of fish catch and aquaculture production since around 1800 are shown. The figure indicates a catch of around 2 million tonnes in 1800, increasing to approximately 20 million tonnes in 1950. Since that time, catches have increased to a 2006 level of around 144 million tonnes. The striking similarity between **Figure 1(a)**, that shows the world population, and **Figure 1(b)**, that shows the global fish catch, results from the fact that fisheries to a large extent have mimicked the change in population and the changes in human activity reflected by increasing

industrialization. Capture fisheries production since 1990 has been roughly level and the growth since then is completely due to increasing aquaculture.

Fishing as a commercial activity can usefully be divided into two elements: that involved with catching and that involved with preserving and processing the catch.

Methods of Catching Fish

There are five main methods.

- **Hooks and lines:** This is perhaps the simplest method of fishing from the earliest times; handlines have been used, but current commercial longlines can be up to 100 km in length.
- **Gill nets:** In this operation, nets are hung from vessels or floating buoys that are largely invisible to the fish, which are caught as they try to pass through the net. Such fishing methods can catch many species other than the main target species and large high seas gill nets are now banned under international treaties.
- **Trawls:** This type of fishing involves a vessel dragging a large net (or trawl). This can be done either through the

Figure 1 (a) World population (Klein Goldewijk and van Drecht, 2006), with permission from Netherlands Environmental Assessment Agency. (b) World fish catch, 1800–2008, including catches from inland fisheries and aquaculture from FAO and Hilborn *et al.*, 2003. Capture fisheries alone were around 92 million tonnes in 2006 (Anon, 2009), with permission from FAO.

water, close to or along the bottom of the sea (demersal trawling), or in the water column (pelagic trawling).

- Seines: The principle of this operation is that a school of fish is encircled by a net, which is then tightened, reducing the circumference of the net until the school is caught. In modern tuna purse seining, a fast motor-boat holds the end of the net steady while the main vessel encircles a shoal of tuna releasing the net as it goes. The net is then pulled in from the main vessel.
- Traps: Fish are usually attracted to a baited trap that allows easy entry but difficult exit. Traps are most commonly used for invertebrates like crabs and lobsters, but many fish can also be caught in traps.

Although the basic methods of fishing are little changed since earliest times, the development of motor vessels to succeed sailing or manpower and the increasing power of engines and gear to locate fish has dramatically increased the fishing power of vessels over the years.

Processing the Catch

Original methods for processing or preserving fish involved sun drying, smoking, salting, and pickling. Subsequent developments as a result of industrialization have involved canning, preserving fish on ice, freezing, and processing on board the vessel, and reduction to meal. Modern factory vessels are highly industrialized operations that catch, process, and package fish, ready for delivery directly to markets.

Changes Since 1945

The industrialization prior to World War II increased the pressure on fish stocks, but the war provided a brief respite as commercial fishing activity was reduced, for obvious reasons. Analyses of this period indicate significant recoveries in major fish stocks that had been heavily exploited prior to the start of the war.

Since then, total fish catch has increased by almost a factor of 5. Much of the increase has come from the coastal regions, where fishing activity has expanded with increase in population, creating more demand for fish products. However, in this period, an activity of global significance has been the development of distant-water fishing by fleets primarily, but not exclusively, of the USSR and Japan. These fleets consisted of large vessels capable of operating for many months away from the home port and with substantial industrial freezing capacities. In the maritime regimes applying in the 1950s and 1960s, these vessels fished the rich continental shelf waters off the coast of many countries. In this period, the catch of distant-water fleets increased from around 500,000 tonnes in 1950 to a peak of 8.5 million tonnes in 1972. The change in the maritime regime brought about by the UN Conference on the Law of the Sea and consequent UN Convention on the Law of the Sea has altered this in a dramatic way. Coastal states have set up Exclusive Economic Zones (EEZs) and restricted fishing on their continental shelf waters. This has resulted in a decline in the proportion of the world fish catch coming from distant-water fleets from 15% in 1972 to 5% by the late 1990s. The most important change has been the stagnation of catch;

there was no increase in capture fisheries production from 1990 and there appeared to be no new significant fish resources to exploit. Any increase in fish production will have to come from aquaculture.

Fisheries Management

The need to manage fisheries as an activity has been recognized since early times, and as long ago as the fifteenth century, Dutch vessels operating in the North Atlantic had a closed season and restricted gear types in order to reduce pressure on fish stocks. Probably with an analogy to farming, it was also recognized that in addition to restrictions on season and types of gear, there was merit in protecting young fish that had yet to breed or fish that were currently breeding. However, regulations were comparatively few and were largely unenforceable except via peer pressure at a local level. The need for management was recognized at an international level after World War II, and a number of international fishery commissions were set up. These varied from the International Whaling Commission, with its focus on whaling worldwide, to commissions specifically aimed at dealing with fisheries in a particular area, which were the most typical. These commissions were set up via international conventions agreed between the coastal states of the region with fishing interests and states with distant-water fishing fleets operating in the area.

It is fair to say that with rare exceptions these international fishery commissions were largely ineffective in directly regulating the level of fishing pressure on fish stocks either via restricting the amount of fishing (effort) or by regulating the catch. The main difficulty was that the commissions typically found the necessary degree of consensus difficult to achieve among states with differing economic imperatives and the commissions relied on countries to enforce regulations on their own fishermen. Most agreements reached concerned readily enforceable regulations such as restrictions on gear types and on fishing seasons. Despite these difficulties, the fisheries management in these bodies was dependent on proper scientific assessment (discussed below) and routinely collected statistics on the catches of species under exploitation. Such data have proved invaluable in assessing the history of exploitation of particular fish stocks and are still of use today. A major exception is the International Pacific Halibut Commission, founded in 1923 which has been very effective. Unlike other commissions, it has only two member nations, the U.S. and Canada.

Post-UN Convention on the Law of the Sea

Since the Law of the Sea convention came into force, the need for international regulation of fisheries by international commissions has been reduced. Most states now have an Exclusive Economic Zone (EEZ) which extends 200 miles from their coast. The reason for 200 miles is that this is an approximation to the extent of the continental shelf where, with very rare exceptions, the vast majority of fish are caught, the nutrient-rich environment providing food for plankton and the fish communities dependent on it. Management in these EEZs has had mixed success, but they do in principle provide

the opportunity for a single entity, the coastal state, to directly regulate the fisheries in the area.

The Current Situation

The UN Food and Agriculture Organization (FAO) has been collecting comprehensive data on fisheries since around 1950. Their figures indicate that the total world catch of fish is dominated by a small group of very large states, or those states that have particularly rich fish resources or a high level of distant-water fleet activities. In fact, 12 countries take around 70% of the total world catch (Table 1).

In the context of biodiversity, the world fish catch is dominated by a relatively small number of species: some 30% of the total world catch consists of only 11 species (Table 2), and the many hundreds of other species caught only form a very modest proportion of this total catch. Nevertheless, fisheries for certain highly valued species such as squid, shrimp, and tuna are extremely important in global terms despite the volume of catch being small.

The development of commercial fisheries in the last three decades of the twentieth century has led to such pressure on fish resources that the paramount question is whether the stocks can continue to sustain these levels of exploitation. Such questions have been posed for a number of decades and it has been recognized for several centuries that over-exploitation can occur unless proper management action is

taken. However, the current situation at a global level is clearly of serious concern. In a 2008 study by FAO, it has been calculated that of those important commercial fish stocks, where sufficient information was available to allow judgment to be made, 52% are fully exploited, 19% are overfished, 8% are depleted with no evidence of any recovery, and 1% are depleted with some evidence of recovery. In other words, almost 70% of the key commercial fish stocks in the world are fully exploited or overexploited and 28% have been depleted to an extent that their capacity to deliver a sustainable yield has been seriously eroded.

The total catch of commercial fish stocks appears to be stabilizing around some 90 million tonnes. It is important to recognize that this apparent stabilization is not an intrinsic characteristic of the biological productivity of the oceans but rather a combination of that productivity and the plethora of individual fisheries that exploit it. Indeed, productivity varies quite significantly from area to area in the world. It is estimated that perhaps 15–20 million tonnes of additional catch could be obtained if all stocks were well managed.

Economic Issues

The historical changes that have led to the current level of overexploitation of the world's fisheries have been paralleled by a somewhat unsatisfactory economic situation. Studies on changes in fishing capacity are relatively few as data are often difficult to come by and changes in overall levels of fishing are difficult to quantify, particularly where diverse regimes and types of fishing vessel operate. However, a recent attempt at synthesis has been made by FAO by referring to the number of decked vessels, which are reported as being licensed by states. The distinction between a decked and an undecked vessel is a reasonable one between primarily commercial vessels, which have a reasonable level of construction, and simple undecked vessels, canoes, etc. Such data that are available indicate that the number of undecked vessels primarily operating in subsistence fisheries in Africa and Asia have remained constant over the past two decades. By contrast, since 1970, the number of decked vessels has doubled. It is worth noting that the vast majority of these increases in vessel numbers have come from one state alone: China. In the period between 1980 and 2005, FAO reported that the number of decked vessels in China increased from 60,000 to 500,000.

This significant increase in the capacity of fleets as measured by the number of vessels also conceals the phenomenon that, on the whole, vessels are getting larger and more technologically sophisticated. Their costs are also correspondingly higher and thus the value and operating costs of the vessels of the world fleet in recent times are likely to be significantly more than those of a few decades ago—certainly more than the simple doubling indicated by the statistics.

In a 1997 study, Garcia and Newton analyzed the behavior of the world fleet in a very simple but informative way. They calculated that the total revenue obtained by the world's fishing fleets (essentially the total first-sale value of the world catch) was less than the costs of operating the fleets by a very large amount. They quoted a figure of some \$54 billion for the operating loss in the year 1989.

Table 1 Fishery catches in 2006 by country (aquaculture not included)

Country	Catch ($\times 10^6$ tonnes)
China	17.1
Peru	7.0
United States	4.9
Indonesia	4.8
Japan	4.2
Chile	4.2
India	3.9
Russian Federation	3.3
Thailand	2.8
Philippines	2.3

Table 2 Fishery catches in 2006 by main species

Species	Catch ($\times 10^6$ tonnes)
Anchoveta	7.0
Alaska pollock	2.9
Skipjack tuna	2.5
Atlantic herring	2.2
Blue whiting	2.0
Chub mackerel	2.0
Chilean jack mackerel	1.8
Japanese anchovy	1.7
Largehead hairtail	1.6
Yellowfin tuna	1.1

How such operating losses are being sustained is an obvious question, to which there is an equally simple answer. These losses have got to be sustainable by either public, i.e., state, or private subsidies of the fishing operations. Given that most fishery operators are small, owning at most a few vessels, it is quite clear that such losses could not be sustained by the private sector and hence it is the state subsidies that are underwriting the continuing losses of the global fleet. In a 2009 study, the World Bank and FAO estimated that there was \$50 billion in lost profits in world fisheries; lost because of excess fleet capacity and fishing effort (World Bank, 2009).

This excess capacity and fishing effort has two unfortunate consequences. First, it means that substantial world resources are being devoted to the continuation of a failing economic activity. Second, vessels are being subsidized to continue in a fishery when normal economic forces would have driven them out much earlier. Hence the fishing pressure on already heavily exploited resources has been continued artificially.

This issue of subsidy in world fisheries has provoked major concern since the work of Garcia and Newton. A recent examination by Milazzo for the World Bank indicated the scale of the problem and showed how substantial and ubiquitous these subsidies are (Milazzo, 1998). Clearly, an immediate removal of subsidies from the fishing fleets around the world would lead to quite unacceptable levels of social deprivation and loss of food supplies. However, the over-capacity of fishing fleets has serious consequences for the continuation of sustainable fishing. States have recognized this and in some areas a reverse process is happening. For example, within the European Union there is a program, the Multi Annual Guidance Program, which is aimed at ensuring, by fiscal means, a reduction in the European fleet. This and other mechanisms for reducing fishing effort are going to be essential if fisheries are to be managed sustainably in the future.

Ecosystem Considerations

Ecosystem impacts of fishing

Much of the discussion in the review so far has focused on the general characteristics of fisheries and it has treated individual fish resources as if they were in isolation from the ecosystem in which they are embedded. However, the level of exploitation that has been occurring has been accompanied, as might be expected from simple ecological principles, by a change in the species composition of the ecosystems that are being exploited. Even in well regulated fisheries the abundance of target species is often reduced by 50–80%, and when fisheries are not well regulated the decline in ecosystem abundance may be much greater. Excess fishing can also cause major changes in trophic structure. Studies have shown that over-fishing cod and other demersal species can lead to major increases in shrimp, crabs, and lobster, which are called “trophic cascades.” Destructive fishing practices such as the use of explosives or bottom trawls and dredges on sensitive habitats can eliminate much of the native biota from an area. Many efforts are underway to ban such destructive practices but it must be recognized that the impacts of bottom trawls and

dredges are very habitat dependent and on soft bottom or habitats subjected to frequent natural disturbance the impact on native biota is much less than on hard bottoms and rarely disturbed habitats.

The Issue of discards

It is well known that certain commercial fisheries operate inefficiently, in that the species targeted are not the only ones to be removed, damaged, or killed. In 1994, Alverson and coworkers (Alverson *et al.*, 1994) estimated that the annual level of discards in commercial fisheries is on average some 27 million tonnes (a very significant portion of the overall total world catch). This occurs primarily in fisheries where the gear, almost by definition, is unselective and unwanted species are caught. The elimination of such discards by gear change and regulation, and the utilization of the catch for human consumption offers a significant potential for increasing overall productivity. Later estimates suggest the level of discarding has declined, in large part to utilization of less valuable species in aquaculture feed, and some estimates are now that the level may be less than 10 million tonnes per year.

Fisheries Science

Although work in the late nineteenth century anticipated some developments, the main pioneers of fishery science worked in the first two decades after World War II. Of the many scientists involved in the development of fisheries as a science, five individuals stand out: Schaefer, an American working at the Inter American Tropical Tuna Commission; Ricker, a Canadian working at the Nanaimo Laboratory in Canada; and three British scientists, Beverton, Gulland, and Holt, all working at the Fisheries Laboratory in Lowestoft. It is their work that set the scene for fisheries science as it is today. All of this work was developed before the availability of modern computing power and the scale of their achievements, set in this context, is impressive.

Maximum Sustainable Yield (MSY)

The basic question of fisheries science is how exploitation and removal of the individuals from a population, affects the dynamics of that population: the processes of birth, growth, and death. A central concept in this exploration is sustainable yield. The idea is simple but it requires an explanation in the context of population ecology. In its unexploited state, a population will on average be in balance with its environment, the processes of birth and growth will be offset by death, and the population will be at equilibrium. A simple differential equation, commonly used in other branches of ecology, expresses this idea well. The rate of change of the biomass B of a population over time is given by

$$dB/dt = rB(1 - B/B_0) \quad [1]$$

When the biomass is equal to B_0 , the rate of change is zero and the population stays at its equilibrium (unexploited) level B_0 . When B is very small compared to B_0 , the population will grow exponentially at a rate r . At intermediate levels, the

rate of change will decline from its maximum at $B=0$, as B increases to zero when $B=B_0$. It is possible to plot the right-hand side of eqn [1] to show how the increase in biomass of a population is affected by its size.

This is done in Figure 2(a). The figure shows that there is a maximum increase in biomass, which occurs at a level where the biomass is equal to $B_0/2$. Some simple calculus can be used to show that this maximum is given by the expression $rB_0/4$. If exploitation is removing biomass from the population, then as long as removals are less than the maximum, they will be replenished by the population. These removals (the yield) are thus sustainable so long as they do not exceed this maximum, which is called the maximum sustainable yield (MSY). The MSY will vary with the abundance of the fish stock concerned (B_0) and its capacity to increase (r).

The exploitation of the population can be modeled by a simple modification of eqn [1]. Let p be the proportion of the population that is removed by exploitation. The equation for exploitation is then

$$dB/dt = rB(1 - B/B_0) - pB \quad [2]$$

This is shown by a simple modification of Figure 2(a) in Figure 2(b).

The expression for the removals pB is a simple straight line with slope p . The larger the proportion removed, the steeper the line. The removals are replenished by the increase in

Figure 2 (a) Rate of change (increase) of biomass related to biomass: The position of stock size when MSY taken is $B_0/2$ and the MSY level is $rB_0/4$. (b) Catch (yield) levels and the rate of change of biomass. Where intersection occurs, an equilibrium yield is being taken.

biomass exactly where the line intersects the curve showing the increase in biomass. Simple calculations can show that where $p=r/2$, the maximum sustainable yield is reached. Where p is greater than this level, there will be a sustainable yield, but it will be less than the maximum and the biomass of the population will be reduced below the level where it produces the maximum sustainable yield. Increasing the intensity of harvesting then will actually reduce rather than increase the yield. By contrast, if p is less than $r/2$, increasing the intensity of harvesting will increase the yield.

In the practical situation, the proportion of the fish stock removed will be determined by the level of fishing effort: the number of boats, their size, the type of fishing gear, the duration of fishing, etc. If the level of fishing effort is less than that required to take the maximum sustainable yield, increasing the effort will result in an increased yield. If, however, the level of fishing effort is higher than that required to take the maximum sustainable yield, further increases in that effort will result in a decrease in sustainable yield. Such a situation is often termed as overcapacity, as removing fishing effort will actually increase yield in the longer term. It should be emphasized that the idea of MSY developed above is an oversimplification and that environmental variability and other factors render its simple application problematic.

The simple models used to illustrate the ideas of sustainable yield and fishing capacity do not allow proper exploration of some of the other key areas of fisheries science. To explore these requires a deeper understanding of the way in which fish populations behave. The idea can be developed simply using an idealized fish population as a subject; here young fish develop from their larval form and become part of the population at a particular time of the year. A year later, they would have grown and some of the cohort would have died, either through predation or other natural causes. The process continues and a typical temperate fish population will consist of a number of age groups, with fewer fish surviving to greater and greater ages. This is illustrated in Figure 3(a).

Exploitation of this population can, in principle, start at any age, but in practice will be determined by fishing methods. For example, the size of the net will determine what age groups are caught; smaller and younger fish can escape through the mesh. Figure 3(b) shows how this will affect the age structure of the population. In the exploited population, fewer fish survive to greater ages and the heavier the exploitation, the more extreme will be the reduction in older fish. However, the biomass of the population is affected not just by natural deaths and fishing but also by growth. As fish get older, they increase in size according to some relationship. Figure 4 illustrates this for a typical fish.

In a comprehensive work first published in 1957, Beverton and Holt explored how the yield could be affected by changing the age at which fishing commenced and the intensity of fishing. Their results show how the interplay between these two parameters, which can be changed by fishing practice, can alter the level of sustainable yield. A centrally important result is that in many cases, delaying the age at which fishing starts to operate can improve yields. This was in part the basis for many national regulations and international agreements to regulate the mesh sizes of nets and the type of fishing gear permitted.

Figure 3 (a) Numbers of fish in each age group in an unexploited population. (b) Numbers of fish in each age group where fishing starts from age 3.

Figure 4 Schematic growth curve for typical fish growth.

Stock and Recruitment

One further element is missing from the description of the dynamics of an exploited fish population: reproduction. Typical fish are enormously fecund, laying as many as several hundred thousand eggs at a time. The eggs and the larvae into which they develop become part of the plankton, where they are subjected to high levels of mortality from predators and from starvation. To illustrate the enormous mortality involved, a male and female fish might produce 100,000 eggs. For the population to replenish itself, neither grow nor decline, two eggs need to survive to adulthood. There are two issues here. The first is conservation, for clearly sufficient adult fish must be permitted to survive to breed to allow population renewal. The second is variability, for it is hard to conceive of a natural process that can provide such control: if on average fewer than two individuals survive, the population is failing to replenish itself; if more than two survive, it will increase. Unsurprisingly, observations on fish recruitment, as it is termed, show high variation. Nevertheless, as more and more fish stocks were heavily fished in the 1980s and 1990s, it became clear that fishing frequently did reduce the number of spawning fish sufficiently to reduce the resultant recruitment (Hilborn and Walters, 1992). Fisheries management agencies now routinely set lower limits on spawning stock and design their harvest strategies to keep stocks above these levels.

Management

The management implications of this analysis are important. If fishing starts on age groups that are not yet mature, then fishing intensity must be controlled to ensure sufficient adults survive to breed so that declines in recruitment do not occur. If fishing does not start on age groups until after breeding has occurred, the conservation issues become less intense, although care is still needed. For example, larger, older fish produce more eggs.

An overexploited fish population will thus exhibit characteristic symptoms. First, there will be few age classes in the population and hence the average age/size of the catch will be lower than in less intensively exploited times. Second, the recruitment of young fish will be in decline, reflecting overexploitation of the adult stock. In such a situation, the management action needed is straightforward, a reduction in fishing intensity and an increase in the age of first fishing. However, depending on the severity of overexploitation, fishing may need to cease altogether.

Although the management action needed to address overexploitation is well understood, once severe overexploitation has occurred, there is no guarantee that reducing or ceasing fishing will reverse the process and that the stock will recover. There are plausible mechanisms that can prevent this, of which the most important are likely to be increased competition or predation by other species. Accordingly, the best fisheries management practice is aimed at preventing overexploitation from occurring.

Monitoring

Clearly, a key to managing fish stocks is the ability to monitor what is happening to the stock under exploitation. There are direct methods of surveying and monitoring stocks using research vessels, which can work well in many cases. Most fisheries management agencies now operate routine surveys of fish abundance for the commercially most important stocks. However, in other situations, such methods are either inefficient or economically unjustifiable. Regular monitoring of

information from the catches of the commercial fleets permits a number of different methods to be used. These methods use this statistical information to reconstruct the behavior of the stock. One common method involves returning to the model of eqn [2]. The yield or catch from the stock was given by the equation

$$\text{Catch} = pB \quad [3]$$

As noted earlier, p depends on the level of fishing effort. The definition of fishing effort (F) is dependent on circumstances, hence for a particular definition of fishing effort, for example, hours fished,

$$p = qF \quad [4]$$

where q is a scaling factor (known in the literature as the catchability coefficient)

$$\text{Catch} = qFB \quad [5]$$

Statistics can provide information on catch for known effort and hence catch per unit of effort (CPUE) is proportional to stock biomass, with the constant of proportionality being the catchability coefficient. A variety of statistical methods exist to estimate the catchability coefficient and as a consequence the stock size. Time series of information on catch and effort thus provides direct insight into the way in which the stock has responded to exploitation.

A second widely used method uses information not just on the catch but on the age composition of that catch. This extra information is used in a method known as virtual population analysis (initially developed by Gulland) to reconstruct the changes in the population under exploitation. The method is simple in conception, although computationally quite laborious. In essence, a simple accounting procedure is used: a catch of 1000 eight-year-olds this year implies that at least 1000 seven-year-olds were alive in the previous year. Adjustments for natural deaths and fish catches then permit the changes in population to be estimated.

Fisheries Economics

It is reasonable to enquire why fisheries are in such a poor state when the science of fisheries is reasonably well developed, methods of monitoring stocks exist, and management actions needed to address overexploitation are understood. The answer lies primarily in the domain of social science.

Fisheries as an economic activity have one fundamental difference from other industrial activities. In manufacturing industry, increases in supply develop in response to demand by increasing inputs of labor, raw materials, capital, etc. In fisheries (and in other industries that exploit renewable resources) there is a limit to supply, which is determined by the maximum sustainable yield. Increasing the inputs to a fishery – more fishermen, better gear, more vessels, etc. – actually reduces the yield if the stock is already being exploited at or above the level of effort that produces the maximum sustainable yield. In this situation, increases in demand reflected in higher prices can lead to increases in fishing effort, lower catches, and hence higher prices. Depending on the

situation, vessels may still be profitable or covering costs even though the effort being expended is well above that required to take the catch and the price paid by consumers well above that, which would prevail if efforts were lower and the catch higher. In a situation where there is no control of the fishery, this process can continue until resources are severely over-exploited and individuals in the industry barely cover their operating costs. The issue is one of ownership; many fisheries are still (and most were) common property resources. In such cases, access is unrestricted and additional effort enters the fishery as long as the return is better than in other activities. Because fishing is a specialized activity (fishing gear and vessels have few alternative uses), other alternative activities offer very low returns. Hence most fisheries, without management tend to be overcapitalized and economic returns are poor.

Most government actions in the period 1970–2000 have been the reverse of what would be economically efficient. Fishing operators have been subsidized and have stayed with the industry rather than leave, thus accentuating the over-exploitation problem. Clearly, social issues play an important role here; it is obviously problematic to let fishing communities face economic collapse, but the scale of subsidy involved is substantial (*see* Economic Issues, above). There have been moves by governments to reduce fishing fleets, either by direct purchase of vessels or by providing incentives to fishermen to use fewer vessels. Fleet sizes in most developing countries declined during the 2000s.

Fishery Management in Practice

The management of fisheries involves some simple principles based on sustainable yield ideas yet its practice is often fraught with difficulty. Management measures typically control fishing by regulations that impose limits on catch (quotas, or total allowable catches (TACs)) or limits on access or effort (licensing, closed areas, and seasons) or by indirect controls such as minimum size of catch or restrictions on types of gear.

It is fair to say that such methods have had mixed success, for a variety of reasons. Control and policing of regulations are difficult and can be extremely costly. Some regulations, TACs in particular, provide an economic motivation for mis-reporting of catches and hence undermine the scientific basis of the process. Political issues, particularly when there is significant overcapacity, can override fisheries management concerns. Often in the face of uncertainty, regulations are set with an optimistic view of the stock, which subsequent scientific information reveals to be unfounded. Even when regulation has succeeded in its conservation goals, the fishing industry remains overcapitalized and continues to need assistance. By 2010 success was more evident as a number of prominent stocks were rebuilding in the US and Europe. In 2011 the former chief fishery scientist for the US government announced that overfishing in the US had ended.

One development where there appears ground for some optimism is the construction by certain states of regimes based on the allocation of property rights to operators: Australia, Iceland, and New Zealand have been particularly active. In these regimes, operators are allocated the rights to a particular level of catch (or proportion of some fixed catch). These rights,

known as Individual Transferable Quotas, can be bought and sold. In this way the inefficient operations can be bought out by the more efficient ones, which can adjust their capacity to the appropriate level for exploiting the fish stock. The attraction of such a regime is that it is in the interests of the operators (owners) to ensure that the stock is exploited sustainably and that the capacity of the fishing fleets matches the production of the resource. Allocation of these individual quotas is highly controversial in some countries because they may lead to concentration of quota ownership in a few companies, and those granted with the initial quotas often become very wealthy on what many view as a public resource. Other methods of allocating exclusive access to fishing based on communities or fishing sectors are being explored as more socially equitable ways of stopping the competitive nature of fisheries.

New International Measures

Although most states now operate 200 mile zones, in which they control fishing, in certain areas the continental shelf extends beyond 200 miles and exploitation of the same stock can be possible both within the 200 mile zone and beyond it on the high seas. The UN Agreement on Straddling Stocks, offers a new international framework for addressing problems of this sort. Its aim is to facilitate the creation of regional bodies composed of both coastal states and those with distant-water fleets operating in the area. It is too early to assess whether this will be successful.

Certain types of species, tuna in particular, are highly migratory and are exploited over very large areas of ocean. Management regimes exist under International Treaty to regulate these fisheries. There are now international organizations for the Atlantic, Eastern Pacific, Western Pacific, and Indian Ocean tuna stocks in addition to a specific organization for southern bluefin tuna. The status of bluefin tuna is of particular concern, and there is a long history of overcatching of agreed quotas and severe depletion of bluefin stocks. In 2010, Atlantic bluefin was proposed to the Convention on International Trade in Endangered Species to have all international trade stopped. The proposal was rejected but was indicative of international concern about the inability of the member countries to set scientifically based quotas and enforce them.

Ecosystem Management

Fish stocks exist in aquatic ecosystems, forming the prey of some species and being predators of others, yet most fisheries science and almost all fisheries management regimes tend to focus on individual species. The regime that was set up to deal with the Southern Ocean, the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR), had a different focus. This regime was specifically orientated to the Southern Ocean ecosystem and regulations were aimed at ensuring that each element of the ecosystem was protected from the effects of exploitation. The primary reason for this markedly different approach was that the large baleen whales of the Southern Ocean had been grossly overexploited by distant-water fleets this century. A significant development of a

fishery for their common prey, krill, could hinder, or indeed stop the recovery of the populations following the cessation of whaling. To date, CCAMLR has been reasonably successful in its operation, setting precautionary levels of catch for krill as well as regulating other fisheries.

However, better scientific understanding of the implications of exploiting groups of interacting species is needed. Current understanding is really little more than educated commonsense – for example, a predator cannot be exploited at its MSY level if its prey is simultaneously harvested at a high level.

The Future of Commercial Fisheries

The increase in the world population over the next two decades will clearly produce an increase in basic demand for food. This is likely to be enhanced in the case of fish as it is a preferred protein source and increasing wealth tends to be associated with increasing fish consumption. Additionally, much of the population increase is estimated to be occurring in Asia, where fish is a preferred source of animal protein.

Statistical analyses of trends in capture fisheries point to a maximum harvest level in the region of 95 million tonnes, a value close to recent average landings. However, more recent analysis by FAO indicates that there is a potential for increasing these catch levels if the full potential of underexploited areas and species was to be realized. Similarly, there is scope, as discussed earlier, for significant improvement in the reduction of unwanted bycatch.

Improved fishery management could, in principle, add significantly to the global production – recall the high proportion of overexploited stocks. However, the extent to which species interactions may mean that the recovery of one stock may lead to lower catches from another is not well understood.

FAO has concluded that a substantial increase in catch levels of around 20 million tonnes could be achieved if (1) degraded resources are rehabilitated, (2) underexploited resources are successfully managed to increase yields, (3) fully exploited resources are not degraded, and (4) discarding and wastage are reduced. This is the challenge for fisheries science and management in the new century.

Glossary

Bulk density The mass of the undisturbed dry soil per unit volume.

Cation exchange capacity (CEC) The capacity of a soil to adsorb cations such as calcium, magnesium, and potassium on the surfaces of soil particles and organic matter.

Dormant/Dormancy Condition under which a seed will not germinate, even if all environmental requirements for germination are met.

Fallow A phase in which no crop is on the land and the volunteer vegetation regrows.

Leaf area index Single-sided total leaf area of the vegetation per unit area of land.

Mulch Retained slash covering soil surface; this can be *in situ* slashed or imported biomass.

Pegging The penetration of the fertilized peanut flower into the soil.

Penetrometer resistance Energy required to push a probe of defined size and shape into the soil.

Transpiration Amount of water taken up by the vegetation and released through the leaves to the atmosphere.

Definition of Slash-and-Burn Agriculture

Slash-and-burn agriculture is a generic term for agricultural systems in which the fallow vegetation is manually slashed, left to dry, and cleared from the field by burning before crop cultivation. "Swidden" is an English dialect word for a burned clearing; thus, swidden agriculture is a synonym for slash-and-burn agriculture. After a cropping phase, the land is abandoned to a fallow phase. Later, the cycle is repeated. Only those systems that alternate between crop and fallow phases are included in this definition. Multistory tree gardens, home gardens, and cocoa plantations, where crops are permanently cultivated, are excluded. With the exception of labor, slash-and-burn farmers use few or no external inputs. Implements such as machetes and hoes are most commonly used. Systems where machinery is used for clearance and irrigated systems are excluded from this definition. Not considered in this context are the systems such as the *ankara* of the Western Highlands in Cameroon, the *nkule* of the Tanzanian grasslands, and the *gy* of Ethiopia, in which vegetation is slashed, gathered, covered with soil, and then burned inside the soil mounds.

Reasons for Slash-and-Burn Agriculture

Most slash-and-burn farmers are poor (*see* Geographic Distribution). Unlike many people in developed countries, they have little choice in how to live their lives. Often the only resource available to them is land. Thus, farming, whether subsistence or market oriented, might be their only option. However, even cash crop production may not provide sufficient income for farmers to change to other economic pursuits. Thus, they remain farmers. Farming methods used reflect the economic constraints of the farmers and tend to minimize labor requirements (*see* Labor Requirements in Slash and Burn Agriculture).

Removal of Biomass

After slashing the vegetation, the amounts of resultant biomass debris on the soil are extremely variable, ranging from

less than 10 Mg ha⁻¹ to more than 500 Mg ha⁻¹ dry matter. Large amounts of biomass make planting difficult and would require too much labor to remove manually. Thus, farmers use fire to remove the biomass, giving easier access to the soil for planting.

Release and Addition of Nutrients from Biomass

Where the fallow vegetation has a high proportion of above-ground biomass as wood, the nutrients bound in it are not easily available to annual crops, as wood does not decompose rapidly. Burning the biomass releases the nutrients.

Weed Avoidance and Weed Suppression

Slash-and-burn agriculture farmers have three principal methods to suppress weed infestation: site selection, the timing of the burn, and tree retention. In forested areas, farmers might choose older secondary or primary forest for clearing because the arable weed seed bank is depleted or absent as the fallow phase has exceeded the seed viability period. If fields become too weedy, farmers may abandon them and clear a new field as the labor requirement for a new clearing may be less than weeding an old field. In short fallow rotations, where the fallow length is insufficient to deplete the weed seed bank, some farmers delay the burn, until a flush of weeds has germinated. These weeds are destroyed in the burn.

Pest and Disease Avoidance

As pesticides are not available to most slash-and-burn farmers, they attempt to avoid crop pests and diseases by appropriate site selection. This option is limited to regions where long fallow phases would withdraw the hosts of pests and diseases for a sufficiently long time to eliminate them. However, pests such as rodents and monkeys would not be affected.

Declining Crop Yields

The combination of nutrient depletion and increasing weed, pest, and disease pressures leads to declining crop yields. After 1–4 years, the field is abandoned to a fallow phase usually because of crop yield declines, or high weed biomass decreasing labor productivity to the point where clearing a new field requires less labor than maintaining an old one. In South America, farmers often abandon their fields when they cannot expect the yield of the subsequent crop to be more than half that of the first crop. However, superimposed on this is the social custom of caring less for cropped fields that are expected to yield less, which accentuates and accelerates any decline. When a cash crop is grown, reasons for abandonment can be external. Farmers in Indonesia reportedly abandoned their slash-and-burn pepper farms, before crop harvest, when the market price for pepper fell.

The Importance of Fallow Length; Long and Short Fallow Slash-and-Burn Systems

Two main types of slash-and-burn agriculture are distinguished, which differ in their effects on the environment: long fallow systems (shifting cultivation) and short fallow systems.

The fallow is the successional vegetation that follows the cropping phase. It may be dominated by trees, shrubs, or grasses, depending on the climax vegetation type, management history, and successional stage. From a utilitarian perspective, its purpose is to reverse the degradative processes of cropping. Here, “degradative” refers to soil fertility decline, weed buildup,

crop pest or disease buildup, or a combination of these. The fallow can act as a weed, pest, or disease break, and fallow vegetation accumulates nutrients in the aboveground biomass, improves soil physical properties through root penetration, and usually permits the recovery of soil macrofauna. Thus, the sustainability of slash-and-burn agriculture depends primarily on the rate of degradation during the cropping phase, regeneration during the fallow phase, and their relative time allocation.

A model of this is detailed in **Figure 1** (modified after Guillemin, 1956). However, the diagram is a simplification and the actual rates of change are unknown. At low human population density, even on nutrient-poor soils, fallow phases may exceed 20 years; thus, the system is case 1 type “long fallow system.” Labor is the main factor limiting the production. For a cropping phase of time a , fallow length ($b + c$) may exceed the optimum. The optimum fallow length, b , is defined as the minimum fallow length required to maintain and maximize crop yields per unit area in the long term and thus occurs just when the system has recovered enough to permit this.

When population densities increase, more land is required and fallow phases are shortened, up to the minimum length required to restore soil fertility (case 2). However, where human population densities increase to the extent that more land needs to be cropped than in case 2, fallows are further shortened and system recovery is not possible. If no additional inputs are made, this can cause soil fertility and weed, pest, and disease problems, and lead to lower crop yields (case 3 type short fallow system).

Figure 1 Degradation and recovery in slash-and-burn systems as related to the cropping interval and when no agronomic adjustments are made. Modified from Guillemin R (1956) Evolution de l'agriculture autochtone dans les savanes de l'Oubangui. *Agronomie Tropicale* 11: 143–176, with permission from Springer.

Geographic Distribution and Characteristics of Slash-and-Burn Agriculture

History

Slash-and-burn agriculture is probably the oldest method of land preparation for planting crops. It was used as a technique in China for establishing rice fields as early as the late Stone Age, 8000–10,000 years ago, and in Mexico at least 5500 years ago, concurrent with the domestication of maize. It was used in Central Europe, along the Danube River, to penetrate the postglacial European forests, for cereal production and, later, in the boreal forests of Scandinavia.

Geographic Distribution

Today, slash-and-burn agriculture is practiced in the moist savanna, the savannah–forest transitional and forest zones of the tropics and subtropics of Central and South America, Africa, Asia, and the islands of Australasia. The majority of countries in these regions have weak economies. Slash-and-burn agriculture is also practiced in other nonindustrial areas, such as Bhutan. An estimated 36 million km² of land is under slash-and-burn agriculture, approximately 30% of the global soil resource. Human population densities in these areas can vary tremendously. In Africa, rural population densities in some parts of the Congo basin are less than three people per square kilometer, yet exceed 400 people per square kilometer in parts of south-east Nigeria.

Labor Requirements in Slash-and-Burn Agriculture

In areas with low population density, long fallow systems predominate. Long fallow systems in forested areas have large land, yet capital and labor requirements are low. Soil fertility, weed, pest, and disease problems are avoided, rather than managed, by shifting to a new field. In the Amazon basin, only 8% of the human energy input to cultivate a cassava field, including postharvest processing, is used for slashing and burning. The energy or labor efficiency of long fallow slash-and-burn systems is the highest among all agricultural systems in terms of energy invested versus energy gained with the crop yield. This is largely due to the absence of fossil fuel use and chemical inputs. However, the destruction of the biomass and the release of the accumulated energy and carbon (*see Consequences of Burning*) in the burn are not considered in such calculations.

In areas with higher population densities and consequently shortened fallow periods, economic conditions become more suitable for market oriented, commercial farming as the higher population densities naturally create markets. Although labor is available, small-scale farmers have scarce financial resources to purchase agricultural inputs. Owing to infrastructural, economic, and soil-related problems of pesticide and fertilizer use, high-input, intensive agriculture is rarely practiced. With reduced fallow length, the labor requirement increases as additional field work, such as weeding and tillage, becomes necessary (*see Effects During the Cultivation Phase*). In short fallow systems of southern Cameroon, land preparation including slashing, burning, and cleaning the soil

surface of unburned debris and weed stumps was 10–13% of the total labor required to establish and harvest a peanut/maize/cassava intercrop.

Although population densities are increasing in many tropical areas and thus fallow periods are shortened, in some situations the reverse has occurred. There were decreases in the population density of the Mayan lowlands, and this was followed by a transition from intensive agriculture to long fallow slash-and-burn systems.

Typical Fallow/Crop Sequences in Slash-and-Burn Agriculture

In West Kalimantan in the mid-1990s, fallow lengths averaged 17 years after a 1-year cropping phase; thus, less than 10% of land was cultivated at any time. Such areas are characterized by low availability of labor and a lack of infrastructure, leading to very limited exchange of products and thus predominantly subsistence farming. In 1996, in southern Cameroon, 32% of fields cultivated had a previous fallow length of 8 years or more or had not been previously cultivated. In the early 1980s, in north Sierra Leone, in the forest–savanna transition zone, most fields had been established from fallows of 30 years or more. Most farmers planted upland rice (*Oryza sativa*) for 1 year before abandoning the land. A minority of farmers followed rice by a peanut and then millet (*Setaria* spp.) sequence before abandonment (Nyerger, 1989).

In long fallow systems, crop diversity within one field can be high. A root or tuber species is often the dominant crop, which is intercropped with other roots and tubers, grains, vegetables, and herbs and spices. In the early 1980s, researchers counted an average of 10 crop species per 25 m² in 3-month-old fields of the Maring people of Papua New Guinea. The dominant crop was taro (*Colocasia esculenta*). Other crops included yams (*Dioscorea* spp.), sweet potato (*Ipomoea batatas*), maize (*Zea mays*), beans (*Phaseolus* spp.), sugarcane (*Saccharum officinarum*), and summer squash (*Cucurbita pepo*). Taro monocrops were also common. In the Colombian and Peruvian Amazon, fields may be dominated by cassava, constituting 80% of crop numbers. In Pará, in the Brazilian Amazon, monocrop maize (*Z. mays*) fields are common and farmers may use fallow 3–30 years old or even primary forest.

In southern Cameroon, four of the most common slash-and-burn field types are as follows:

- The *essep* or long fallow or primary forest conversion field used to gain title to the land. This is approximately 0.25 ha and a few larger forest trees are retained. Relatively shade-tolerant crops, particularly tannia (*Xanthosoma sagittifolium*), egusi melon (*Cucumeropsis mannii*), and plantain (*Musa* spp. AAB) are grown with many minor crops. After the plantain harvest, the fields are either abandoned for 20 or more years or burned and recultivated after 1–4 years to plant a peanut/maize/cassava field.
- The peanut/maize/cassava field (*Arachis hypogaea*, *Z. mays*, *Manihot esculenta*) with plantains (*Musa* spp. AAB) and leafy vegetables as minor components. Fallow length is 8–10 years near the border with Equatorial Guinea yet 2–4 years near the capital city, Yaoundé.

- Monocrop horticultural systems, particularly tomatoes (*Lycopersicon lycopersicon*) or maize for fresh consumption. These fields are most common close to the capital and external inputs, both inorganic and organic, are used.
- *Musa* spp. (banana and plantain) monocrops or perennials such as oil palm (*Elaeis guineensis*) and cocoa (*Theobroma cacao*). These are usually established after long fallow forest clearing with *Musa* often intercropped with the perennials.

Clearly, slash-and-burn systems can have high or low crop diversity. This does not depend on eco-region or population density, but rather on the preferences of the farmers.

Effects of Clearing at Field Establishment

Farmers in different parts of the world use slash-and-burn techniques, yet their goals may vary. These range from completely and irreversibly removing the initial vegetation to retaining a rich repository of indigenous and useful plant species while introducing crops. Elaborate clearing and tree-felling techniques have been developed by different indigenous cultures to facilitate the drying and burning of biomass. These techniques are summarized by Peters and Neuenschwander (1988).

The types and numbers of trees retained vary considerably, depending on the tradition of the farmers and their intentions. However, usually very large high-canopy trees are not felled because it is not worth the considerable effort involved, it would require paying for the labor of a skilled chainsaw operator, and the felled tree would take up a considerable part of the plot. Other trees retained include those producing fruits, nuts, or medicine, or those believed to maintain or enhance soil fertility or have a commercial value. Such retained trees are a source of seeds, although many such species do not necessarily establish in an environment imposed by slash and burn. Furthermore, these trees can harbor many species of animals and possibly host microsymbionts. The retention of trees in slash-and-burn fields can facilitate the return of the initial vegetation, depending on the stand density of trees retained and the size of the clearing.

Reductions in tree densities through slash and burn or other forms of clearance may affect densities and species numbers of arboreal and litter-dwelling ants. Yet these species may also have a role in pest control. In areas cleared of forest in the Amazon, it was found that isolated trees can retain considerable ant diversity, although the species composition was not identical to that of the nearby forest.

When slash-and-burn farmers in the forests of West and Central Africa clear for a peanut/maize/cassava short fallow field, they completely clear the fallow vegetation and remove all trees so that there is abundant light for these crops, which do not tolerate shade. Additionally, as any mulch layer would impede peanut growth and pegging, the farmer attempts a complete burn. The soil is tilled by hoeing after burning and weeding is frequent to reduce competition. In contrast, the root, tuber, and plantain crops of the “essep” field can be planted even if trees are retained, and if the slash is not completely burned, the soil is not tilled and weeding is neither as intensive nor as frequent as in the short fallow fields.

Partial or complete removal of vegetation has differential effects on the microclimatic and hydrological conditions after clearing. Soil temperatures are usually higher in cleared areas and even higher when the slash is burned. The absence of tall vegetation leads to a different redistribution of rain, as less or no rain will be intercepted in the canopy. Raindrops reach the soil surface with their full impact, potentially contributing to compaction and crust formation at the surface. Surface compaction can lead to temporarily ponding water at the surface and, if on sloping land, can cause erosion. Furthermore, crust formation can impede the gas exchange between soil and atmosphere, resulting in deteriorating conditions for the soil fauna and flora.

Slash-and-burn fields have lower biomass than forests, and crops do not cover the land for the entire year. The leaf area index of crops may not be as high as in a forest; thus, transpiration is lower. With reduced transpiration, water flux through the soil is increased, which can increase mineral losses due to leaching. The root systems of crops have to grow for each cropping cycle, whereas in the forest the root system of the trees remains in place and potentially adds exploited soil volume every growing season. Access to and uptake of water at the start of the rains is thus immediate in forest. Rooting depths of crops are restricted to the upper layers of the soil, whereas forest vegetation roots may penetrate deeper layers drawing on water during dry seasons, not accessible by and available to food crops. The more permanent canopy and root system of forest contributes to less strong fluctuations of most climatic and hydrological factors.

Consequences of Burning

Heat Evolved during the Burn

Few studies have measured the heat evolving from the burning of slashed biomass. The amount of heat evolved depends on the amount of biomass and its water content. Climatic conditions during the burn, such as wind speed, and topographic features, such as the aspect and slope of the field, have an impact on the intensity of the burn and the maximum temperatures attained. Slash-and-burn agriculture in savanna regions or in short fallow systems, where small amounts of biomass are burned, does not cause significant heat-related effects on the soil. Temperatures at the soil surface are relatively low, heat penetration into the soil is limited to a depth of 1–2 cm, and the exposure time to the heat is short. However, even fast burns, which do not attain high temperatures, can kill seeds lying on the soil surface. There are no reports of light burns affecting seeds buried in the soil.

Burning of cleared forest biomass, depending on its water content, can reach 800 °C near the soil surface, and these temperatures will be maintained for a longer period. If temperatures reach 400 °C, soil organic matter may be lost by combustion, resulting in decreases in soil organic C and N. Clay particles may fuse, altering the soil texture and its cation exchange capacity (CEC). The spatial variability of temperatures is higher in a cleared forest than in short fallow or savanna systems. The boles of large trees may burn for more than a week, evolving large amounts of heat and depositing

large amounts of ash in a small area. In southern Cameroon, on an Ultisol, the maximum temperatures attained during burning of 3000 Mg ha⁻¹ of wood, equivalent to a bole of approximately 0.65 m diameter at a wood density of 0.6 Mg m⁻³, were 788 °C at the soil surface, 225 °C at 5 cm, 172 °C at 10 cm, and 105 °C at 20 cm depths. The burn lasted for approximately 24 h. Such severe burns usually kill plant seeds even in deeper layers and reduce living microbial biomass in the soil, including mycorrhizae, rhizobia, and other microsymbionts. Further, all soil meso- and macrofauna are affected, depending on the temperature reached and the soil depth to which it penetrated.

Soil, Soil Nutrients, and Soil Physical Properties

Depending on the intensity and size of slash-and-burn clearing, local consequences range from nutrient inputs from the atmosphere such as sulfur dioxide and flying ash to changes in microclimate and increased variation in rainfall pattern, and influxes of pests, diseases, and invasive weeds.

Many soils in forested areas of the tropics have a low nutrient status, aluminum toxicity problems, high levels of phosphorus fixation by iron oxides, and a low CEC due to the dominant kaolinitic clays, which are also susceptible to structural collapse under mechanization. Where the fallow vegetation has a high proportion of aboveground biomass as wood, the nutrients bound in it are not readily available to annual crops, as wood does not decompose rapidly. Burning the biomass releases the nutrients, and, with the exception of nitrogen and sulfur, a large proportion will remain in the ash on the soil surface. Although the nitrogen is almost entirely lost to the atmosphere, the sulfur, as sulfur dioxide, can be redeposited as sulfuric acid near the burn, if the humidity of the air is high. When the fuel (biomass and debris) is very dry, the burn is fast and hot and strong upward air currents result, which carry away the ash particles. Windy conditions during the burn will increase such losses. In the Amazon, element transfer to the atmosphere due to ash particle transport and volatilization has been reported as up to 98% C, 98% N (these actually being inevitable losses), 33% P, 31% K, 24% Ca, and 43% Mg of the initial amounts in the fuel. Sulfur losses to the atmosphere were estimated between 69% and 76% of that in the original biomass.

Wood ash contains calcium, magnesium, and potassium in the form of phosphates, carbonates, silicates, and other elements. The nutrients in the ash are partially water soluble and will be released into the soil solution with the rain. Thus, slash-and-burn agriculture makes nutrients available to crops. Although farmers realize the fertilizing effect of the ash, they are more concerned about achieving complete burns to remove the biomass. The longevity of increases in calcium, magnesium, and potassium concentrations in the topsoil depends partially on the CEC. Although the increased calcium concentrations are likely to be long term because of low calcium mobility and solubility, magnesium and particularly potassium are prone to leaching. Experiments in southern Cameroon showed the fertilizing effect of ash to be very short lived and not exceeding the first two rainy seasons after a burn. Burning usually reduces soil organic matter content. On

kaolinitic soils, much of the CEC is on organic matter; thus, a reduction in organic matter will reduce CEC and increase the risk of leaching. In southern Cameroon, it could be shown that increases in exch. K were measurable down to 50 cm within 6 months of burning forest biomass.

However, with the rain dissolving the ash, soil pH usually increases rapidly to above pH 8 and remains high for some months. Topsoil pH usually increases after burning. In soils where aluminum toxicity problems occur, burning reduces extractable aluminum concentrations and increases phosphorus availability.

It has been reported in the literature that the burn loosens the soil and facilitates tillage and planting by reducing bulk density and penetrometer resistance. Direct measurements in southern Cameroon could not confirm these reports. Farmers experience the forest floor to be difficult to penetrate with tools before the burn, probably because of the dense network of small but woody roots in the litter layer and close to the soil surface. The litter layer and the roots will be destroyed in the burn and will no longer be an obstacle. Furthermore, attempts to work the soil before burning are made on dry soil, which is harder, whereas planting after the burn usually happens after some rains have softened the soil.

Hot and long-lasting burns such as under a tree bole produce white ash. The soil color changes to bright red, and compaction and a collapse of its structure can be observed. This is probably due to a relative excess of monovalent cations that lead to a breakdown of cation bridges between clay minerals, the combustion of soil organic carbon and thus substances binding soil particles, and the elimination of soil macro- and microfauna mixing soil particles and organic materials to form stable aggregates. Slash-and-burn farmers recognize such areas in their fields and usually do not plant crops there.

In savanna regions with small amounts of biomass, the effects of burning on the soil are not discernible. Ash inputs do not cause a measurable increase in pH or cation concentrations. Neither soil organic carbon nor total soil nitrogen is affected by such light burns. In grass fallows, the amounts of biomass may not be an obstacle to planting. However, the quality of the slashed biomass is low. Biomass retention as mulch would have adverse effects on crop growth, because soil nitrogen might be immobilized in the decomposition process, causing nitrogen deficiency for the crop.

Most slash-and-burn agriculture systems use only the *in situ* slashed vegetation. There are, however, systems such as the *chitemene* system in southern Africa in which wood from a larger cleared area is collected and concentrated in a smaller area where it is burned. Farmers seek nutrient augmentation or concentration in the topsoil by piling large amounts of wood on the soil surface. The wood is transported to the field from the surrounding Miombo woodland. The area cleared may be up to 20 times larger than the field in which the wood is burned, adding large quantities of nutrients. Although this system appears to be designed to concentrate nutrients, its efficiency in retaining these nutrients remains low. In an experiment conducted in Zambia, 84% of the phosphorus contained initially in the vegetation was accounted for by increases in the top 50 cm of soil at 40 days after burning. However, 57% of this phosphorus was at 20–50 cm depth,

in a region already inaccessible to any growing crop. For potassium, only approximately 10% of the original input was retained by the top 50 cm of the soil at 40 days after burning. The remainder presumably had leached below 50 cm depth.

In other systems, only part of the biomass is burned while a certain portion is used for other purposes such as fencing the field against animals, as fuel wood, or for construction.

Soil Bacteria and Fungi

Burning can reduce living microbial biomass in the topsoil and potentially their decomposing activities. However, there are reports that burning increased microbial biomass and activity in tropical savanna and in a tropical plantation forest. It has been shown in Kenyan soils that total bacteria counts dropped after burning. Nitrogen-fixing bacteria are very susceptible to pH changes after burning. Such effects of the burn on microsymbionts can subsequently affect the composition and productivity of the vegetation as certain species may depend on symbionts.

Many crops have mycorrhizae and are able to access organic phosphorus using the enzyme phosphatase in a hydrolysis reaction. Thus, although burning can increase phosphate availability, if it reduces mycorrhizae, overall effects could be negated, depending on whether the crops grown are mycorrhizal and whether the planting material is infected. Studies in India comparing vesicular-arbuscular mycorrhizal (VAM) infection of plants in burned and nonburned areas of a tropical forest found that infection was reduced in burned areas. However, studies from wet tropical forests in Costa Rica found that mycorrhizae survived burning.

Invertebrates: Soil Fauna

The soil fauna are only directly affected by the burn if they are present in the topsoil during the burn. As fields are usually burned toward the end of the dry season, groups such as earthworms are usually withdrawn in deeper soil layers and thus are not directly affected by the heat. However, after burning large amounts of biomass, the ash is dissolved in the first rains. This solution is very high in pH (up to 10). Such solution infiltrating the soil might kill certain species that usually live under rather acidic conditions under the previous forest cover (pH of approximately 4.0–4.5 in most tropical forests).

Weeds

Severe burns usually kill plant seeds even in deeper layers and can reduce the weed seed bank. Although burning is believed to reduce weed pressure, it can facilitate weed invasion. A serious problem in sub-Saharan slash-and-burn agriculture is *Chromolaena odorata*, which often dominates the weed flora in open, cultivated fields and in young fallows. *C. odorata* seeds have higher germination rates when they are exposed to light on the soil surface. Thus, airborne seeds can colonize newly burned fields. On the contrary, where slash is retained, seeds fall onto the slash, which dries out quickly, preventing

germination. Once established, *C. odorata* plants can survive burning as their woody stumps may remain unaffected in the upper soil layers. Generally burns have little damaging effects on species regenerating from rootstocks or rhizomes. Often such species are favored in systems exposed to fire because burning destroys seedlings of other species and thus can reduce competition from other weeds. *C. odorata* and *Imperata cylindrica* are typical examples of species being favored by regular fire.

Other Plant Species

Slash-and-burn agriculture in a tropical dry deciduous forest in Mexico eliminated 29% of resprouting species, particularly those that were present at low abundance. This reduction was exacerbated by repeated burning.

Vertebrates

The effect at field establishment and specifically at burning depends on the species and its mobility. Although mammals may escape the slash and the burn by moving into surrounding unaffected vegetation, many reptiles and amphibians are killed when forest is cleared and burned, as they cannot escape quickly. Depending on the season and the temporal pattern of activity, animals that hibernate through the dry season may escape the fire if burning happens before larger rains have fallen. Where vertebrate and particularly mammal and bird densities decrease after slash-and-burn agriculture, the potential for fallow recovery may be reduced because many vertebrates are responsible for seed dispersal.

Effects during the Cultivation Phase

In traditional shifting cultivation with long fallows, the cropping phase lasts 1–4 years. As the length of cultivation increases, the potential of land to recover to its initial vegetation is reduced. Operations such as tillage and weeding frequently disturb the soil, and the viability of seeds of the initial vegetation is reduced. Regrowth from stumps is slashed more frequently, increasing the risk of dieback. There are changes in microclimatic and edaphic conditions that may reduce the probability of survival of species of the initial vegetation. In addition, the cropping phases are windows for weed invasion, and a return of the initial vegetation may be severely impeded by species such as *I. cylindrica* and *C. odorata*.

Tillage

The traditional shifting cultivator does not use many tools to work the soil. Most crops are planted with a simple planting stick or by opening small planting holes with a machete or hoe. Most crops, such as cassava, tannia, taro, plantain, melon, and maize, do not require tillage to succeed. If slash and burn is practiced in short fallow systems in degraded land, crops such as melon and plantain are not grown as they are considered not to produce well, whereas other crops can perform well but require tillage. The soil is tilled either to mix the ash

with the soil, to bring the seed to the required planting depth, or to concentrate nutrient-rich topsoil around the crops (mounding). Most intensive soil disturbance is caused by tillage for crops such as yams (*Dioscorea* spp.), which are mounded; peanuts (*A. hypogaea*), for which the soil is tilled at planting and a second time before pegging; potatoes (*Solanum tuberosum*), and sweet potato (*I. batatas*), for which ridges or small mounds are made. Farmers throughout have made their own observations and know which crops respond positively to tillage. However, tillage is a labor-intensive operation and is more frequently used where labor availability is high and soil fertility is low.

Tillage disrupts the natural layering of the soil and breaks up soil aggregates. Naturally formed pores (earthworm channels, termite and ant galleries, and root channels) are interrupted and often are filled with loose fine material. Soil fauna dwelling in such pores will be negatively affected by tillage, as their habitats are destroyed or the number of potential niches is reduced. Tillage changes the water regime in the topsoil and might lead to a more rapid drying out of the top layer, causing stronger moisture and temperature fluctuations. Soil mites and springtails respond to such fluctuations by withdrawing into deeper layers, which may be less rich in substrate and thus do not permit the same level of activity and population densities.

When land is cleared, slashed, burned, and tilled, earthworm density, diversity, and activity are reduced. This has been shown in south-west Nigeria, where the earthworm fauna is dominated by *Hyperiodrilus africanus* and the epigeic *Eudrilus eugeniae*, in the Peruvian Amazon, in southern Cameroon, and in south-east Mexico. Earthworms are classified functionally into epigeic, anecic, and endogeic categories. Epigeics live in the litter layer. Anecics feed on litter and soil, dragging litter into their vertical burrows. Endogeics live in the soil and feed on soil organic matter and dead roots. Anecic and epigeic are the groups most immediately affected by slash, burn, and tillage due to the loss of current and future substrates and physical habitat disruption. These groups will take longer than endogeics to recolonize the soil and litter layer under the recovering fallow.

Tillage affects the seed bank in the soil. This is less important in long fallow slash-and-burn systems as seeds will normally be on the soil surface where they are most likely to be killed by the burn. In younger fallow, with light burns, not all seeds on the soil surface may be killed. Where the land has been previously cultivated with tillage or any soil-moving operation has been conducted (harvest of root and tuber crops), a seed bank consisting of the buried portion of seeds protected from the effect of subsequent burns already exists in the soil. Buried seeds can become dormant and survive for several years. Tillage after the burn will move such seeds closer to the soil surface, increasing their chance of germination, whereas other, younger ones may be buried and become dormant.

Weeding

Most weeding operations are conducted with the same or similar tools as tillage. Therefore, in addition to the tillage, weeding affects the soil, soil inhabitants, and the weed seed bank. It is difficult to separate the terms "seed bank" and "weed seed bank," as the same species may be both: a weed in the cropping phase and a desired plant in the fallow phase of a

slash-and-burn rotation (cycle). Moreover, many slash-and-burn farmers tend volunteers that are considered food or vegetables, and they retain these species often until the seeds are mature, assuring the same species being present in a following cropping phase. To simplify, all nonplanted species will be treated as weeds in the cropping phase, except for the desired volunteers. The weeding of a field, established after forest clearing, will eliminate seedlings and reduce stump regrowth of forest species. Depending on the cutting height and the frequency of weeding, these species may eventually die. When the land reverts to fallow, these species will be unable to reestablish immediately. The fallow may thus consist only of weeds from the cropping phase.

Pest and Disease Suppression

Certain pests and diseases of crops may be avoided by choosing land that was under fallow for a long time. The efficiency of pest and disease avoidance depends on the distances between fields, the mobility of pests, and the vectors by which pests and diseases are spread. Soil-borne diseases might be affected by the dramatic soil chemical changes after the burn and the associated increase in soil pH and the changed microclimate. One important mechanism in pest and disease suppression, not directly related to "slash and burn," is the complex mixture of crop species in slash-and-burn fields. Up to 40 species might be planted or tended within a single plot. Pest and disease buildup is not possible or is strongly delayed if the organisms are confined to a few isolated plants. The large number of pests and diseases with their different ecological requirements does not permit a general statement of the effects of slash-and-burn agriculture on their presence and severity in crops.

Radopholus similis is a plant-parasitic nematode, cosmopolitan in the tropics. It is the greatest cause of yield loss in bananas and plantains worldwide. Peanut and maize are also hosts, as are *Commelina benghalensis* and *Fleurya aestuans*, minor components of weed and fallow communities in West and Central Africa. *R. similis* does not survive in the soil for more than 6 months when host roots and corm pieces are absent. Thus, even a single-year fallow can prevent infection of the following crop, if *C. benghalensis* and *F. aestuans* are uprooted and the new planting material is pest free. The Maring people of Papua New Guinea plant banana suckers into their field during the burn. Heat would penetrate the outer layers of the banana sucker and would be likely to kill nematodes infecting the planting material. Other peoples roll banana suckers in ash before planting, this is believed to both kill nematodes and have a fertilizing effect.

Certain crop diseases are affected by the degree of shade in the plot. For example, the fungus *Mycosphaerella fijiensis*, the causal agent of black sigatoka disease of plantains and bananas causes less damage to bananas when they are grown under shade trees than when they are in full light. *Mycosphaerella musicola* is the less virulent yellow sigatoka, dominant at higher altitudes. Workers in the Caribbean, Central America, and Africa have noted that when trees are eliminated from slash-and-burn fields, these diseases destroy larger areas of the leaves and yields are reduced by up to 40%.

Nowadays, short fallow slash-and-burn farmers have a limited choice of land, but in some areas, they have access to pesticides. With a broad range of crops and more recently intensive vegetable production, the use of pesticides has become more common in many developing countries. Slash-and-burn farmers, although as yet rarely, do increasingly resort to pesticide use. Although any pesticide may be targeting a specific pest or disease, it usually affects other organisms as well and indirectly organisms relying on the affected nontarget organisms. With often little knowledge of the effects of pesticides on slash-and-burn agriculture, cultivators may destroy organisms, important to the ecosystem's functioning. [Thurston \(1992\)](#) provides a very comprehensive description of pest and disease control in such low-input cropping systems.

Management of Crop and Weed Residues

Some effects of slash-and-burn land preparation are aggravated by crop management. In natural vegetation, in both long and short fallows, litter will accumulate on the soil surface, contributing to reduced soil temperature and providing nutrient and substrate inputs. During the cropping phase, some crops produce litter, and uprooted or cut weeds could be retained as mulch. Yet mulching or simple retention of such residues is not a common practice amongst slash-and-burn farmers. In most cases, litter and weeds are removed, thrown outside the field, or piled on tree stumps. In the Congo basin forest zone, tree stumps with weed residues are often covered on purpose to prevent the stump resprouting or to accelerate rotting of the stump. Retaining residues may create niches in which some of the fauna may survive the cropping phase. Yet slash-and-burn farmers are aware that mulch can also provide potential niches for pests.

Nutrient Export through Crop Harvesting

In addition to unproductive nutrient losses (combustion, wind, leaching, erosion, or transfer to unavailable forms), the harvested crops contain nutrients that are exported from the field. As slash-and-burn crop yields are usually low, crop export losses are considered marginal compared to other losses, especially at burning of old fallows. However, in short fallow systems, which produce less biomass and thus have a lower nutrient input from the fallow, with more frequent or prolonged cropping phases, the crop nutrient export losses will become more important in the overall nutrient balance of a field.

Effects of Prolonged Cropping Phases

Prolonged cropping phases permit the invasion of weeds suited for conditions in a clearing. Such weed species die out if the field is abandoned after a short cropping phase and if the previous vegetation establishes rapidly. However, if the cropping phases are prolonged, these weeds have more time to establish, produce seeds, or propagate by vegetative means such as rhizomes. Consequently, competition between crops and these invasive weeds increases, and once farmers no longer consider cropping a suitable option, these weeds may

be so abundant that they reduce or even eliminate the chances of recovery of the initial vegetation. Often the ability of the initial vegetation to return is further reduced by repeated burning. Repeated burns kill tree stumps and seeds and can select for grasses (Poaceae), which may initially establish from seeds but often propagate by rhizomes in the soil and thus are less affected than other species by the burn. The result is that the plot may revert to "arrested succession" grassland and be rendered unsuitable for cropping in the medium term. This may be a goal of a farmer who wishes to create pasture or may be an unintended consequence. In south-east Asia, prolonged cropping after forest clearing has facilitated the invasion of the land by *I. cylindrica*.

Generally, climax forest species have seeds that remain viable for a short time. Thus, extended cropping phases will compromise the regeneration potential of the forest. However, where the intended purpose is to repeatedly crop after short fallow phases, the absence of viable seeds of forest species is academic, as they would have no possibility to establish on that site.

Effects during the Fallow Phase

The effects of slash and burn on biodiversity in the fallow phase are strongly related to the conditions prevailing during the cropping phase. In long fallow systems with short cropping phases, the transition into a fallow dominated by pioneer trees is fast, without a phase in which arable weeds dominate. In the highlands of Papua New Guinea, the Maring people tend the resprouting trunks of the pioneer tree rokunt (*Saurauia* sp.) in their fields near the end of the cultivation phase, even though these compete with their crops. Seedlings of *Casuarina oligodon*, a nitrogen-fixing tree, are transplanted to the field at this time to enhance soil fertility recovery during the fallow. Such reestablishment of the fallow vegetation will probably ensure the reestablishment of the soil micro-, meso-, and macrofauna. With an increased length of the cropping phase, fields tend to get weedy as species not existing in the previous fallow might have established in the cultivation phase. These are likely to form at least part of the first fallow succession community. In such a situation, the establishment of a fallow vegetation as before the slash-and-burn cycle is delayed, and in some cases impossible.

Biomass production and nutrient uptake and cycling are the primary processes of soil fertility restoration. The amounts of biomass and nutrients accumulated are a function of the fallow length. The minimum fallow length to completely restore soil fertility ([Figure 1](#), case 2) will vary depending on soil type, the types of weeds, crop pests and diseases present, and the growth rates, composition, and succession of the fallow species.

Aboveground biomass accumulation rates of forest fallows vary between sites and may vary between fallow ages. Most data from 4-year-old fallows range from 24 to 56 Mg ha⁻¹, for 8-year-old fallows from 40 to 150 Mg ha⁻¹, and for older fallows up to 500 Mg ha⁻¹. Biomass accumulates for at least the first eight years. Some authors have reported that half the biomass in a 20-year-old fallow had already accumulated by the fourth year. In contrast, others show that accumulation

rates of approximately $5.5 \text{ Mg ha}^{-1} \text{ year}^{-1}$ remained constant from the 4th to the 15th year.

Generally, soil organic matter levels increase with time under fallow. During 4 years of bush fallow in south-west Nigeria, soil organic carbon content increased by 46% and total nitrogen by 59%. A 15–20-year-old fallow had soil organic matter levels of 3.8% compared with 1.1% in cultivated plots. In the drier region of north-east Brazil, a 10-year-old fallow was sufficient to restore soil carbon and nitrogen levels to those under undisturbed vegetation. Many authors have reported that soil organic matter and soil nitrogen concentrations do not increase substantially after 8–10 years of fallow.

Occasionally, farmers use indicators to judge when to clear and crop a fallow. In south-west Cameroon, farmers stated that there is a definite minimum fallow time to regain fertility, expressed in years but judged by the type and maturity of the vegetation growing there. The Turumbu of Yangambi in the Democratic Republic of Congo (formerly Zaire) judged when to break fallow by the girth of umbrella trees (*Musanga cecropioides*) and the biomass of the undergrowth. They cleared when they could walk easily beneath the trees. These secondary considerations coincided with soil fertility regeneration (Jurion and Henry, 1969). In south-west Nigeria, farmers claim to use the appearance of the vegetation cover and the presence of particular plant species and of earthworm casts to decide whether a fallow is ready for cropping.

In Papua New Guinea, bird and reptile species diversities were low in young fallows, but increased as succession proceeded. Reptiles were less affected than birds. The bird communities in young, grassy fallows were dominated by obligate granivores, whereas the forest supported specialist feeders (frugivores, nectarivores, and branch gleaners). Butterfly species richness showed a similar pattern.

In southern Cameroon, species richness of birds in *C. odorata* fallow was only a fifth of that in secondary or primary forest. Butterflies and termites had similar magnitudes of declines. Canopy ants and canopy beetles were completely absent in such fallows, given the near-absence of trees. The species richness of flying beetles, leaf-litter ants, and soil nematodes was not different between forest and young fallow. Presumably, the young fallow, located within a mosaic of recovering fallows and secondary forest, provided sufficient food and suitable conditions for their continued survival. For more details, see Lawton *et al.* (1998).

In southern Cameroon, earthworm activity, indexed by surface cast production, declined rapidly after forest clearance, burning, and cropping and did not recover during two years of fallow. At the same site, cast production decreased after clearing, burning, and cropping a 4-year-old *C. odorata* bush fallow, but did recover during the fallow phase. The change in living conditions from forest to cropland was probably too drastic for the existing earthworm community to maintain its activity level. A new community structure comprising species capable to cope with the new conditions could not establish within 2 years of fallow. On the contrary, the community in bush fallow had probably already undergone some shifts, thus recovering as soon as bush conditions were reestablished. The response of termites was different. In both forest and bush clearings, termite densities dropped to approximately 1% of densities in the retained forest. There was no recovery during

the fallow phase. The number of species in the cleared area was only half as high as in the forest.

The Scale Dependence of the Effects Caused by Slash-and-Burn Agriculture

Topographic Preferences and Fragmentation

Slash-and-burn farmers have topographic preferences. Long fallow farmers often prefer gently sloping land as this facilitates the burn. They avoid slopes that are too steep as this increases the risk of soil erosion. Yet their choice is limited by the type of terrain available. In other parts of the tropics, farmers prefer the plateaus and avoid cropping even on the gentle slopes. Valleys fringes, although difficult to access and waterlogged during the rainy season, are under greater pressure from farmers for dry season cropping of high-value market crops. In contrast, riverine forests and swamps are avoided and therefore can remain undisturbed.

Such preferences result in fragmentation. Ultimately, in areas of high population density, fragments of the previously contiguous vegetation will remain only in areas unsuitable for agriculture. Not all species of plants and animals are represented in such fragments of vegetation, and thus a recovery of the surrounding to the initial condition is not possible. However, if slash and burn occurs in particular topographic positions in low population areas where systems have sufficiently long fallow to restore the forest, it does not have major effects on biodiversity.

Temporal and Spatial Scales

Traditional systems at low population densities, with small fields (0.25–3 ha) in 1-year cropping phases and long fallows of 20 years, use 5% of the land at any given time (Figure 2). Fields are surrounded by fallow land at various stages of recovery. Even if the fields are cropped for up to four years, not more than 20% of the land will be cultivated. Recolonization of a cleared plot by species from the surrounding fallow occurs rapidly after farmers stop weeding or abandon the land. The rate of recolonization by animals depends on the species' mobility. Plant species' invasion or recolonization of the site depends on the species' type of seed and the method of seed dispersion. Unless species are extremely immobile or, in the case of plants, if the fallow length is too short for species to reach the reproductive phase, this system can maintain the initial biodiversity.

With increasing human population densities, slash-and-burn agriculture is practiced in shortened bush or grass fallow cycles, with prolonged cropping phases. Both processes lead inevitably to a larger proportion of land being under cultivation. This occurs rapidly when fallows are shorter than 10 years in systems cropping for more than 1 year and when fallows are shorter than 5 years in systems cropping for 1 year (Figure 2).

Topographic preferences and an increasing proportion of land cropped at any given time lead to larger scale fragmentation, with areas of the initial or recovering vegetation isolated by larger areas of cropped land and early stages of fallow. Spatial fragmentation can compromise the following: (1) the

Figure 2 Proportion of cultivated land at 1–4 years of cropping phases, as a function of fallow length.

ability of the remaining undisturbed or recovering habitat fragments to maintain diversity, which determines the potential to recolonize the disturbed habitats, and (2) the ability of species to be dispersed to and establish in disturbed areas. Both aspects depend on the species investigated. Generally, with increasing size of an animal species, spatial requirements for foraging and hunting increase, and thus their chances of survival diminish with increasing fragmentation. A number of additional factors, such as mating habits and the ability to cross disturbed areas to reach other undisturbed fragments, will modify the likeliness of species' maintenance. Smaller animals, largely invertebrates, might not be affected as severely by fragmentation as larger animals. On isolated trees retained in pastures in the Amazon, a considerable diversity of ants was found, with a large proportion of species usually found in the forest. Ant diversity was positively related to the epiphyte load of trees.

Fragmentation of forest by pasture land such as in the Amazon basin negatively affects certain tree species retained in the forest fragments. Some species need cross-pollination to produce seeds. If fragments become too small or too distant from each other, the tree density might fall below a threshold required for pollen to reach other trees. Such a process, observed in mahogany (*Swietenia macrophylla*), reduces or eliminates seed production and may lead to local extinction.

The potential to regenerate degraded land to the initial vegetation and habitat depends on seed dispersion and mobility of animals. Seed dispersion by birds, bats, and monkeys has been shown to be important in disturbed and undisturbed areas. However, in Uganda, it was shown that bats and birds did not considerably contribute to the dispersal of forest species' seeds to degraded grassland areas. The vast majority of seeds moved by these animals belonged to species dominantly found in disturbed areas or to species unable to establish in the grassland. Similarly, seed dispersion by gibbons confined to small forest fragments after large-scale slash-and-burn agriculture in Kalimantan was found to be uncertain as individuals were extremely hesitant or unable to cross cleared areas to reach other fragments.

The effects of slash-and-burn agriculture on biodiversity are various. However, generally, the shorter the cropping phase

and the longer the fallow phase, and the smaller the proportion of cropped land, the greater the possibility of recovery of the previous vegetation. However, these criteria limit the productivity of slash-and-burn systems. To maintain their livelihoods, the choice for many farmers whose land allocation is fixed is either to prolong the cropping phase or to shorten the fallow phase. Clearly, research should also compare and contrast the effects of these options on biodiversity, rather than focusing exclusively on comparisons with undisturbed ecosystems that are increasingly unrepresentative.

Alternative Systems to Slash-and-Burn Agriculture

Plantations of Perennial Crops and Trees

Plantation systems include monocrop oil palm, fast-growing timber species, coconut, rubber, tea, coffee, and cocoa. Most plantation systems are established by slash and burn. Timber plantations are often established in forests by selective felling or poisoning of undesired trees, underbrushing, and sometimes light burning of the understory. In such systems, the forest habitat is only slightly altered and reestablishes quickly. In southern Cameroon, timber plantations had similar levels of termite species richness to secondary forests and more species of leaf-litter ants than both secondary and near-primary forests (Lawton *et al.*, 1998). However, the dominance of one tree species may affect the underbrush regrowth and the conditions for soil fauna through a narrower range of substrate. Many plantations, such as oil palm, coconut, rubber, tea, and other species, which demand full sunlight, are planted after clear-cut felling. Depending on the intensity of cropping, these plantations may be frequently weeded and treated with pesticides. Under such conditions, biodiversity may be greatly reduced. In contrast, cocoa plantations in southern Bahia, Brazil, are established in old secondary or primary forest. Cocoa is shade tolerant, so although the lower-canopy trees and herbaceous components are slashed, many upper-canopy trees are retained. These include many valuable timber species, rosewood (*Dalbergia nigra*), pau Brasil (*Caesalpinia espinata*), and cedro (*Cedrela odorata*), that have been nearly eliminated elsewhere by loggers. Consequently, associated fauna have been maintained, including rare primate species, for example, the sagui (*Callithrix kuhlii*) and the lion tamarin (*Leontopithecus rosalia*).

Pastures

In large parts of the Amazon basin and in Central America, forest is clear cut to establish pastures. Although in tree and palm plantation systems, a forest-like microclimate will be reestablished after some years, pastures will remain unshaded. Any forest regrowth is regularly slashed, and in some situations, pastures are regularly burned to reduce forest regrowth and promote grasses.

Improved Short Fallow Systems

Slash-and-burn agriculture is demanding on the natural resource base, irrespective of the fallow type (forest or short

fallow). It requires large areas for cultivation as yields are low. In many situations, the natural regrowth in short fallow systems is not capable of restoring soil fertility because of the shortened period of time available in which the volunteer regrowth cannot produce sufficient biomass and accumulate sufficient amounts of nutrients. Improved fallow systems seek to replace the, usually undesired, volunteer regrowth by species that produce more biomass faster, contain more nutrients, or produce a type of biomass that is of a different physical structure than the natural regrowth. Such species are expected to out-compete the weed flora quickly and not to contribute to propagation or maintenance of crop pests and diseases. Often legumes, fixing atmospheric nitrogen, are used to augment the nitrogen resources of the soil.

Improved fallow can be based on tree, shrub, or herbaceous species. Depending on the fallow type used for improved fallows, the biomass is either slashed and burned or only slashed and retained as mulch. Tree- and shrub-based systems are likely to be cleared and managed in the same way as older natural fallows because the large proportion of wood in the slash can be removed only in a labor-efficient way by burning it. The extensively researched alley cropping system in which trees were pruned and the prunings were mulched has not been accepted by farmers, mainly due to its labor requirements and poor crop yield responses in farmers' fields (Hauser *et al.*, 2006). Systems using herbaceous legumes, such as *Mucuna pruriens* or *Pueraria phaseoloides*, reduce the number of plant species surviving in the fallow, and *P. phaseoloides* has been shown to reduce plant parasitic nematode densities. Depending on the crop planted after herbaceous fallow, the slashed mulch can be retained as a mulch layer, retaining soil fertility, protecting the soil from compaction and erosion, and rendering good living conditions with minimal disturbance to soil invertebrates. Although such systems will not maintain biodiversity similar to that in forest, the increased crop productivity (yield increases up to 100% for maize) and the option to crop the land at higher frequencies than in natural fallow cycles (*Pueraria* 1–2 years of fallow; *Mucuna* often annual cropping with 6–8 months of fallow) allow farmers to remain on the same land and, theoretically, reduce their need to clear forest or older fallow, although social customs to gain title to land may dictate otherwise. With less land used for agricultural production, more land may be retained in undisturbed condition and provide for the long-term retention of biodiversity.

Slash-and-Burn Agriculture and Carbon Sequestration

The environmental credentials of slash-and-burn systems have been questioned globally as vegetation burning releases stored carbon to the atmosphere as carbon dioxide. The global average aboveground biomass of secondary humid forests is approximately 450 Mg ha⁻¹, although there is much variation; thus, assuming a complete burn, up to 200 Mg ha⁻¹ C can be released to the atmosphere, equivalent to approximately 730 Mg ha⁻¹ of CO₂. In addition, carbon dioxide release from the soil may occur as exposed soil organic matter and decaying roots decompose. The quantity of CO₂ released will depend on the initial forest biomass and climatic conditions governing decomposition during phases after the burn. Yet given that

many slash-and-burn systems are no till or minimal till, soil carbon losses through accelerated decomposition rates of soil organic matter may be much less than in mechanized systems.

Furthermore, food crops will assimilate less carbon from the atmosphere than the initial vegetation would have assimilated, thus reducing the C-fixation in biomass and contributing to a larger release of carbon in the cropped plots during the cropping phase. Carbon sequestration during the cropping phases is low. While maize in slash-and-burn systems produces 4–6 Mg ha⁻¹ of aboveground biomass within 3–4 months, 50–75% is straw, which remains on the field and will decompose in the following months, and the maize cobs are removed from the field and consumed. Cassava may produce between 20 and 40 Mg ha⁻¹ total biomass (aboveground and belowground combined), yet approximately 50% of that biomass are roots that will be removed. Thus, cropping phases generally do not sequester significant amounts of carbon.

Data on biomass accumulation during fallow phases are rare and highly dependent on the fallow vegetation. In southern Cameroon, the dominant short fallow species *C. odorata* produced approximately 11 Mg ha⁻¹ of aboveground carbon including litter within a 2-year fallow period. Two shrub fallow systems using the species *Flemingia macrophylla* and *Dactyladenia barteri* produced approximately 13 Mg ha⁻¹ aboveground carbon including volunteer species and litter. A tree fallow system with *Senna spectabilis* produced 26.5 Mg ha⁻¹ aboveground carbon including volunteer species and litter. Thus, the fallow type has a considerable effect on the amount of C that is sequestered. Even if all aboveground fallow carbon is burned, the time-average C stocks are higher in the tree system than in any other. Considering aboveground carbon accumulation in crops is 10 Mg ha⁻¹ year⁻¹ and carbon accumulation in the fallow phase is linear, the tree system holds, on average, 16.5 Mg ha⁻¹ carbon per year versus 8.8 Mg ha⁻¹ in the natural fallow system. During longer fallow phases, carbon accumulation at Yangambi (Democratic Republic of Congo) was 40 and 61 Mg ha⁻¹ in 5- and 8-year-old fallows, respectively. Carbon accumulation curves tend to be sigmoidal with initially low rates in the first 2 years, followed by higher rates, and then level off as stands age.

When calculating “ecological footprints” of slash-and-burn agriculture, the carbon dynamic of all fallow stages in the slash-and-burn cycle needs to be considered. While carbon is released in the newly cut plot and minimal carbon storage occurs during the cropping phase, carbon assimilation occurs in the various fallow phases, so the net impact of the system is likely to be a small loss or in equilibrium, assuming that fields remain in the long fallow cycle. Furthermore, slash and burn is conducted predominantly by people who make negligible demands on global fossil energy resources.

Modern systems integrating short rotation forestry with agricultural production may offer reasonable C sequestration rates combined with food production and the option to replace fossil fuels. In Cote d'Ivoire, Benin, and the Democratic Republic of Congo, acacia plantations were established for timber or charcoal production. Such plantations are cut after 8–9 years at an estimated 80–100 Mg ha⁻¹ standing tree biomass (not including litter and roots) or 36–45 Mg ha⁻¹ of C, which is equivalent to a time-average C stock of 19–24 Mg ha⁻¹ year⁻¹. The trees are either sold as building

material or converted to charcoal. The residues are burned *in situ*, and the land is cropped and replanted to trees for the next cycle. Crop yields were reported to be higher after such plantations than after similar aged natural fallow, dominated by grasses, in Benin and Congo, yet not in Cote d'Ivoire. If trees are used for construction, the C will be sequestered. Charcoal production and use will ultimately return all sequestered C to the atmosphere, yet replaces at least partially the use of fossil fuel. Thus, slash-and-burn systems can be designed to hold substantial amounts of C and to produce materials that will retain C over long phases, yet farmers' food production and income generation needs and targets need to be considered to make these systems more attractive.

Glossary

Biodiversity of forests Variability in genetic structures, species composition, and habitat properties in forest ecosystems.

Boreal forests A forest zone dominated by coniferous species, covering the northern latitudes of North America, the Nordic countries, and Russia.

Forest management Manipulation of the properties of tree populations or modification of the properties of the habitats occupied by these populations.

Sustainable forestry Management and utilization of forest resources in a way that balances human needs with undisturbed functioning of the forest ecosystem, and a long-term maintenance and sustainability of the resources and biodiversity of forest ecosystems.

Timber industry Any kind of forest-based production using timber as a raw material.

Main Features of Boreal Forests, with Special Reference to Finland

Forests currently cover about 4030 million hectare (Mha), or 31% of the world's land surface, and represent the largest land-based ecosystem types in the world. Forest species, along with related species communities and ecosystems, represent a large proportion of the global biological diversity and are of great importance in maintaining the functioning and structure of the biosphere. The boreal forests alone represent an area of 1700 Mha and account for about 20% of the world's industrial timber supplies. Commercially, the most important coniferous species are pine (*Pinus*), spruce (*Picea*), fir (*Abies*), larch (*Larix*), juniper (*Juniperus*), thuja (*Thuja*), and hemlock (*Tsuga*), whereas the most common deciduous species in these forests are aspen (*Populus*), birch (*Betula*), willow (*Salix*), and alder (*Alnus*).

The boreal forests in northern Europe or Fennoscandia (including Norway, Sweden, Finland, and northwestern Russia) are probably the most intensively utilized of all; that is, they form 80% of the total forest area in Europe (1005 Mha) and provide about 40% of the timber used in Europe (Table 1). The stocking ($68 \text{ m}^3 \text{ ha}^{-1}$) and growth rate ($1.1 \text{ m}^3 \text{ ha}^{-1} \text{ year}^{-1}$) in these forests are substantially lower than in more southerly regions, however, and consequently

the timescale in forest production is long, with rotations of 40–160 years according to species and region. Growth and felling are currently well balanced, and the growth may even exceed the needs of the timber industry.

Forestry in northern Europe is mainly based on native tree species which invaded this region postglacially. In Finland, for example, Scots pine (*Pinus sylvestris*) is the dominant species throughout the country (about 45% of total stem volume) wherever nutrient and water supplies are limited at the site. Scots pine can also dominate at more fertile sites, but both Norway spruce (*Picea abies*) (about 37% of total stem volume) and birch (*Betula pendula* and *Betula pubescens*) can win out over it under such conditions. Birch species (about 18% of total stem volume) are most common on the most fertile soils.

In contrast with many developing countries, forest coverage in Fennoscandia has remained at the current level for decades or even increased slightly. Forest utilization in Finland has been occurring for centuries. Toward the late 1800s Finnish forests were intensively used for slash-and-burn cultivation and tar production without any actions to promote new tree generation. As a result, large areas, especially in southeastern Finland, became dominated by relatively young forests 100 years ago. Effective prevention of slash-and-burn cultivation and forest fires together with active timber-oriented

Table 1 Main features of the Boreal Forest Zone in Europe

		Balance (Mm^3)	+ 235

management have led to an increase in the areas of closed-canopy forest during the past century.

In general, the number of species per unit area is low at northern latitudes. This also holds for Finland, where the estimated total number of species is about 50,000, of which about 43,000 are known. The reason for the relatively low total number of species is the short time that has elapsed since the last glaciation (10,000 years), with the consequence that immigration is still occurring. These species and the subsequent biodiversity involve a large contribution from natives of the eastern taiga (e.g., flying squirrel, Ural owl, and Siberian jay). Most of these taiga species are connected with spruce forests. Furthermore, the amount of dead or decaying wood is generally high in boreal forests, especially in the early phase of the succession after a fire or windstorm. Consequently, a high proportion of the forest species (20–25%) are dependent on dead wood (800 coleopterans, 1000 dipterans, 1000 fungi, 200 lichens, etc.). Many of these species are also specialized in living on recently burned tree material, whereas a high proportion lives in peatland forests or on mires. Most of these species need a moist and shady habitat.

Dynamics of Boreal Forest Ecosystems and Management Implications

Management: Control of the Structure and Functioning of the Forest Ecosystem

Forests are ecosystems in which trees and other green plants occupy the site and intercept solar energy under the control of climatic and edaphic factors (Figure 1). The interaction of populations with their environments forms complex food webs, in which the solar energy flows from producers to consumers. The links between the organisms are the key to the management of a forest ecosystem. Proper manipulation of

forest dynamics will allow the production of timber or other items, with the management needs being related to the management objectives and to the changes in the structural properties of the forest ecosystem occurring with time. The management history and past structure of a forest ecosystem may also have a crucial impact on future management. Production in a forest can be maintained and increased by manipulation of the genetic properties of the tree populations or modification of the properties of the habitats occupied by these populations. This takes place by controlling the long-term functional and structural development of the forest ecosystems (the forest succession) in order to induce them to produce the items defined in the management goals. In other words, any kind of forest-based production is a result of environment, genotype, and the interaction between these.

Successional Dynamics of Forest Ecosystems and Management Implications

The long-term growth and development of tree populations are subject to disturbances due to wind, fire, and attacks by pests and pathogens. Under boreal conditions in particular, such disturbances cause cycling in the dynamics of the forest ecosystem by returning the succession to an earlier phase. For example, a fire that kills old trees provides space for regeneration. For larger forest areas, this implies that forest landscapes contain a mosaic of tree stands of varying species composition and age, from open areas and saplings to mature trees.

During the succession, each stand or part of the mosaic undergoes a gradual change involving alterations in species composition and the accumulation of organic matter in trees and soils (Figure 2). Many broad-leaved tree species can make better use of the abundant supply of resources at fertile sites than can coniferous trees. Broad-leaved species typically dominate the initial phase of the succession after a fire, and

Figure 1 Schematic presentation of the structure and functioning of a forested ecosystem as an interaction between climatic and edaphic factors and the populations of organisms, with implications for management.

wherever site fertility is sufficiently high the changing conditions will later start to support shade-tolerant conifers more than the broad-leaved trees. This brings an invasion of conifers such as Norway spruce to the site, which finally replaces the broad-leaved species unless a disturbance causes the succession to return to an earlier phase. These disturbances and the dynamics of the tree species result in substantial variability in the mass of organic matter in forest ecosystems. This cycling determines the management of the forest ecosystem and the timber yield obtained.

In terms of the energetics of the ecosystem, the energy intercepted by the trees and other green plants and the energy used at different trophic levels in the ecosystem's food webs is balanced by means of enhanced formation of dead and decaying wood and other organic matter. In this context, the food webs provide complex feedbacks through which the populations of the various species interact, with consequent control of the ecosystem dynamics. The food webs tend to increase in complexity during the succession.

Disturbance Dynamics of Forest Ecosystems and Management

The disturbance dynamics of forest ecosystems provide the framework in which management occurs. Two categories of disturbance may be distinguished which drive the succession: autogenic and allogenic (hence, we may speak of an autogenic

Figure 2 Schematic presentation of the course of total growth (P_G), net growth (P_N), respiration loss (R), and the accumulation of mass (B) in trees during the succession.

or allogenic succession). Allogenic and autogenic successions are typical processes operating simultaneously in boreal forests.

In the autogenic succession, the structural dynamics of the forest ecosystem are driven by the regeneration, growth, and death of single trees, that is, minor disturbances related to their life cycle (gap-phase dynamics). The deaths of single trees and the consequent gaps in the canopy release resources and enhance regeneration and growth. The concept of autogenic succession is applied in the form of selection forestry or uneven-aged management, in which single trees are the basic object of management. This system is widespread in the temperate zone, in which autogenic succession predominates in the dynamics of forest ecosystems.

Allogenic succession refers to dynamics driven mainly by major disturbances induced by fires, gales, and excessive snowfall. Under these conditions many trees may die simultaneously, releasing space for new trees to regenerate and grow to form a population with individuals of more or less the same age (cohort-phase dynamics). In allogenic succession the stand is the basic unit driving the structural dynamics of the forest ecosystem. The concept is applied to management in the form of standwise forestry, or even-aged management, in which single stands form the basic object of management. This system is commonly employed in the boreal zone, in which allogenic succession predominates in the dynamics of forest ecosystems.

Management involves the use of a variety of measures to control the supply of resources and the properties of tree populations. The measures used to control the supply of resources may be classified into two categories in relation to the disturbances driving the succession methods liberating resources to a large extent (allogenic measures related to the allogenic succession) and methods liberating resources to a lesser extent (autogenic measures related to the autogenic succession) (Table 2).

Allogenic measures mainly control the properties of the soil system, and subsequently the nutrient cycle and soil moisture, with the greatest enhancement of growth and regeneration of pioneer species being achieved through disturbance of the soil surface. Site preparation refers to

Table 2 Schematic presentation of the effects of given management measures on site properties and tree populations^a

Measure	Effects on site properties and populations				
	Nutrients	Moisture	Temperature	Soil physics	Species
<i>Allogenic measures</i>					
Site preparation	+++	++	+++	+++	+++
Ditching	++	+++	++	++	+++
Prescribed burning	+++	+	++	++	+++
Fertilization	+++				+++
Regenerative cutting	++	++	++	+	+++

Selection for regeneration	+	+	+	+	+
Precommercial thinning	+	+	+	+	+++
Commercial thinning	++	++	+	+	++
Pruning	+	+	+		+

^a +, Slight effect; ++, moderate effect; +++, substantial effect.

mechanical measures used to reduce the effects of the ground vegetation on saplings and to adapt the physical and chemical properties of the soil. In this context, ditching is aimed only at lowering the groundwater level and reducing excess soil moisture. Prescribed burning affects the chemical properties of the soil and eliminates ground vegetation interference with sapling growth. Fertilizing implies the addition of nutrients at the site, leading to a substantial increase in the availability of nutrients for tree growth. Regenerative felling refers to terminal felling aimed at promoting reforestation of the site through natural regeneration by means of natural seeding or artificial regeneration by means of the sowing of seed or planting.

Autogenic measures are mainly represented by spacing, leading to enhancement of growth and regeneration among both pioneer and climax species. This is achieved through the thinning of sapling stands (precommercial thinning) and more mature stands (commercial thinning). The tending of sapling stands is aimed at proper spacing, as is also true of thinnings, and it also implies the elimination of unwanted tree species. Pruning involves the removal of dead or living branches from the lower crown in order to increase the amount of knot-free wood obtainable from the stem. Selection for regeneration refers to the removal of single mature trees or small groups of mature trees in order to create canopy gaps in which seedlings can become established and grow.

Management of Forests for Optimal Productivity and Timber Production

Among the key issues to be addressed in management is the optimal distribution of tree species and stand age (or tree size) over the forest area in order to maximize long-term growth. Assume a forest area of 100 ha to be divided into six compartments (stands) allocated to initial age classes (i.e., 2, 10, 22, 38, 82, and +82 years) in different ways. Calculations by Kellomäki (1998, pp. 225–226) show growth during the next 10 years to be highest in the stand with an initial age of 38 years, with this growth being five times that in the stand with an initial age of 85 years. Consequently, a distribution skewed toward dominance by old stands represents the highest level of stocking but about 15% less growth than that for a normal distribution (Figure 3). Where young stands are dominant, the total growth is only one-third of that for a normal distribution, whereas an even distribution gives 70–80% of the total growth achieved with a normal distribution.

In the short term, the maximization of timber production would thus require an age structure representing a normal distribution, that is, a forest area that is fragmented into single stands of variable age and stocking with the inevitable impact that this will have on species with a habitat corresponding to mature or old-growth forests. In the long term, this age distribution will gradually lead to dominance by old stands, with increasing stocking and decreasing growth – a situation that is less than optimal for timber production. Terminal felling of stands previously of intermediate age but now mature will lead to a shift in the age distribution toward dominance by young stands with low stocking and absolute growth but high

relative growth. The maximization of timber production over several rotations in a sustainable manner thus requires that the forest area should be divided into sections representing a mix of sapling, pole, and mature stands in such a way that the overall age distribution implies dominance by pole stands with high stocking and high growth. The forest area will still be fragmented in this case, which will mean major impacts on species with a preference for mature or old-growth forests.

Impacts of Timber-Oriented Management on Biodiversity: Comparison between Managed and Natural Forest Areas

Impact Mechanisms

Among the key issues in managing biodiversity in commercial forests is the maintenance of the functional and structural properties of the forest ecosystem, which will create and maintain heterogeneity among the habitats available for species to occupy. Two levels of heterogeneity may be distinguished: allogenic heterogeneity between stands and autogenic heterogeneity within stands. These concepts are related to allogenic and autogenic succession. Allogenic heterogeneity creates a landscape mosaic, whereas autogenic succession creates further heterogeneity within each element of the mosaic in terms of an even-aged stand structure or multilayered tree canopies (Table 3). The contribution of allogenic and autogenic heterogeneity to the total heterogeneity of the landscape is probably multiplicative rather than additive.

The total impact of forestry on the availability of suitable habitats is difficult to predict. The optimization of age distribution for timber production may increase allogenic heterogeneity and fragmentation of the landscape. In particular, the remaining patches of mature or old-growth forests may be too small to sustain viable populations or too isolated for recolonization of areas where a population has temporally become extinct. Simultaneously, management may reduce autogenic heterogeneity in two ways. First, it may avoid or even curb successional processes that give rise to within-stand structural components and spatial patterns that are important for forest biodiversity (Table 2). Second, regeneration practices and precommercial and commercial thinnings can reduce or even remove autogenic heterogeneity. This tendency is quite obvious in standwise management, especially if pure single tree populations in even-aged stands are preferred for reasons connected with timber production.

The critical question in the previous context is to what extent it is possible to maintain in commercial forests the processes, structural components, and patterns typical of mature or natural forests as listed in Table 3. Many of these elements are interrelated, and practically all are somehow related to different types of disturbances and the subsequent succession. The amount of coarse woody debris is highest during the early successional phases in natural forests, whereas in managed forests no dead or dying trees are left at this stage. The scarcity of such debris (dead and decaying wood) is generally accepted as the main reason for the disappearance of many species from the boreal forests that are being managed

Figure 3 Computational example of how the age class distribution of tree stands can influence the productivity of a forest area. Distribution of tree stands with an overall area of 100 ha: (a) no single age class dominant (even distribution), (b) dominated by intermediate age classes (normal distribution), (c) dominated by young age classes (distribution skewed to the left), and (d) dominated by old age classes (distribution skewed to the right). (e and f) Stocking and growth, respectively, over the forest area for the various distributions.

for timber production. In Finland, for example, more than 20% of the species with a preference for forest habitats are dependent on dead wood (e.g., there are about 1000 fungi and about 800 beetles whose occurrence is related to the presence of such material). This implies that 36% of the total number of species threatened by forestry practices are ones whose occurrence is related to the presence of dead wood.

It was not known for certain until recently whether species depending on dead wood require closed-canopy old-growth habitats or whether they could make use of younger successional phases if a sufficient amount of dead wood was available. Recent evidence suggests (Figure 4) that the latter may be possible and that many threatened species may survive in managed forests if certain properties typical of natural forests are maintained or even increased. However, many threatened species have highly specialized habitats, for example, sand ridges, riverbanks, or large, overmature aspen trees (*Populus tremula*). The majority of these key habitats are of marginal importance for timber-oriented forestry since they represent

sites of low productivity or are quite small in extent. Given careful planning and management, these key habitats could be set aside, which could have a major impact on the conservation of threatened species which prefer forest habitats. Along with measures to increase dead wood in commercial forests, this would provide new possibilities for reducing the impact of timber-oriented management on threatened species.

Properties of Forests under Intensive and Extensive Management: An Example

The impacts of timber-oriented management are exemplified in the following by referring to a comparison of selected beetle populations in an intensively managed forest area and an extensively managed one with a quite different management history (Siitonen and Martikainen, 1994; Siitonen *et al.*, 1995). This material also provides a unique opportunity to contrast our current understanding with experimental data representing the long-term effects of forestry on the properties

Table 3 Structural components, spatial patterns, and processes important for biodiversity in natural forests but lacking or altered in managed stands

Processes

Postfire succession
Succession with tree species replacement
Self-thinning
Gap formation
Snag and log formation
Decomposition of coarse woody debris

Structural components

Very old pine and spruce trees
Old broad-leaved trees, particularly aspen and willow
Trees with abundant growth of epiphytic lichens
Broken, stag-headed, and leaning trees
Trees with holes and cavities
Dead standing trees (snags)
Fire-scarred trees, snags, and stumps
Large fallen logs in various stages of decomposition

Spatial patterns

A developed understory of tree saplings and shrubs
Mixed stands with both conifers and broad-leaved trees
Uneven-aged stand structure
Multilayered tree canopies
Patchy distribution of trees

Figure 4 Volume of standing dead wood in different successional stages of managed and natural Norway spruce stands (data provided by Anneli Uotila, University of Eastern Finland).

and biodiversity of boreal forests. The studies of Siitonen and Martikainen (1994) and Siitonen *et al.* (1995) are widely used in the following discussion.

The two areas are located on either side of the border between Finland and Russia (62 or 63° N, 30–32° E) (Figure 5). Before World War II, both areas belonged to Finland and were utilized and managed in similar ways. The border, created in 1944, split them in a biogeographically random manner.

The forests on the Finnish and Russian sides of the border have been used and managed quite differently for the past 50 years. Those in Finland have been subject to intensive use and a form of management that has included balancing growth

Figure 5 Landsat image (27 May 1992) of part of the forest area on both sides of the border between Finland and Russia. Water is indicated in blue, young forest in red, and mature forest in green (Siitonen *et al.*, 1995).

with felling, systematic regeneration in the form of plantations established in clear-felled areas, or natural regeneration by means of seed trees or shelter wood fellings in favor of coniferous species. Precommercial thinnings and intermediate thinnings have been used to reduce the role of deciduous trees, and the latter have also been used to harvest the growth and yield that would otherwise have been lost in the natural self-thinning associated with the succession. Furthermore, the length of the rotation has been determined with the aim of maximizing the timber yield (80–100 years), which has further reduced the formation of dead and decaying wood. Additional reductions in dead wood have been achieved by effective fire fighting and the logging of trees blown down by storms or broken by heavy snowfall. The small-scale ownership of forest plots has further enhanced the fragmentation of the forests as each owner has aimed to maximize her or his timber yield and income.

On the Russian side of the border, clear-felled areas were not systematically regenerated, and thus fertile sites were occupied by mixtures of coniferous and deciduous trees. Since no precommercial thinnings or intermediate thinnings took place, the dominance of deciduous trees throughout the rotation was substantially higher than on the Finnish side. Later, dying trees were not logged in connection with thinnings, with the consequence that there is now a large amount of dead and decaying wood present. Furthermore, a low utilization rate of stems and the leaving of deciduous trees of low commercial value in the clear-felled areas were characteristic of logging practices. Simultaneously, uncontrolled forest fires were common and timber destroyed in other natural disturbances (e.g., storms and heavy snowfalls) remained unharvested. In other words, human intervention in the regeneration and growth of the forests has been substantially less than that on the Finnish side of the border.

Landscape and Local Patterns in Relation to Management

Systematic field samples from both sides of the border and analyses of satellite images indicated that the mean area of

individual tree stands was quite similar but old-growth stands were substantially larger on the Russian side. Furthermore, the largest areas covered by homogeneous tree stands were larger on the Russian side. Most of the large stands on the Russian side were the result of extensive forest fires. However, the number of separate stands relative to the total area was larger on the Finnish side, that is, the Finnish forest landscape is more fine grained and fragmented. This difference is quite evident even on the satellite image, which indicates the dominance of a coarse-grained landscape on the Russian side (Figure 5).

Closer analysis of the properties of the forests shows that deciduous tree species are more common in the Russian forests than in the Finnish ones throughout the area (Figure 6). Mature aspen in particular has been effectively eradicated from the Finnish forests because of its tendency to host a serious fungus disease that affects sapling stands dominated by pine. The most striking differences, however, concern sapling stands on fertile sites, which are dominated by Scots pine and Norway spruce in Finland but both Pendula and Pubescent birch in Russia. Coniferous tree species naturally dominated the sapling stands on poor sites in Finland, but they also did so on fertile sites, whereas in Russia deciduous species exceeded 20% of the total number of stems per hectare even on poor sites in many cases. In other words, the forest cover more frequently represented a mixture of tree species on the Russian side than on the Finnish side.

In terms of dead and decaying wood, the difference between the two areas was clear; that is, the mean amount of dead wood in the Finnish forests was $4 \text{ m}^3 \text{ ha}^{-1}$ (range

$0.1\text{--}26 \text{ m}^3 \text{ ha}^{-1}$) and that in the Russian forests was $29 \text{ m}^3 \text{ ha}^{-1}$ (range $0.1\text{--}213 \text{ m}^3 \text{ ha}^{-1}$) (Figure 7). It is worth noting that the amount of coarse woody debris is high even in sapling stands in the Russian forests (up to $79 \text{ m}^3 \text{ ha}^{-1}$), mainly as a result of forest fires. Here, the dead wood represents mainly dead trees (standing and lying), whereas in the Finnish forests it mainly comprises logging residues (stumps, branches, and tops of stems). These patterns held good over the whole range of variability in fertility and the age of sites and stands.

Beetle Fauna in Forests under Intensive and Extensive Management

Siitonen *et al.* (1995) assessed the impact of forest management on biodiversity in terms of the number of beetles species caught with window traps operating over one growing season. The total yield was about 29,000 individual beetles representing 623 species. There were no major differences in the total number of species or in the main groups of species, except for the species preferring dead wood, with the consequence that the total number of saproxylic species was 179 in the Finnish forests and 213 in the Russian ones (Table 4).

It was found that 17 of the 20 most frequent species with a preference for dead wood were more frequent on the Russian side of the border. These represented mainly species with a preference for decaying birches (e.g., *Trichius fasciatus*, *Hylocoetus dermestoides*, *Leptura quadrifasciata*, and *Anaspis arctica*) or for the final phases of decay in coniferous trunks

Figure 6 Tree species composition of sapling stands, pole stands, and mature stands in areas on the Finnish and Russian sides of the border (Siitonen *et al.*, 1995).

Figure 7 Volume of dead wood as a function of tree species and maturity of tree stands on the Finnish and Russian sides of the border. Spruce forest represents higher fertility than pine forest (Siitonen *et al.*, 1995).

Table 4 Total numbers of Beetle individuals and species as a function of their dependence on the occurrence of dead wood (Siitonen *et al.*, 1995)

Parameter	Finnish forests	Russian forests	Total
<i>No. of individuals</i>			
Obligatory saproxylic	3645	4964	8609
Facultative saproxylic	1893	2202	4095
Other species	8657	7663	16,320
Total	14,195	14,829	29,024
<i>No. of species</i>			
Obligatory saproxylic	179	217	253
Facultative saproxylic	55	58	64
Other species	245	232	307
Total	479	507	623

(e.g., *Anoplodera virens*, *Ampedus balteatus*, *Ampedus tristis*, and *Hadrobregmus pertinax*). The numbers of common and fairly common species in both countries (found consistently less than 25 times in Finland) were very similar, but the number of the rarest species (found consistently less than 12 times in Finland) was substantially greater on the Russian side (Table 5).

The occurrence of species with a preference for dead wood was related to the amount of dead wood present in the tree stands, as shown in Figure 8. However, there was no correlation between the occurrence of other species and the amount of dead wood. The numbers of specimens of other species

were inversely correlated with the basal area of trees in the stand, however, which implies that there are more beetle species in sapling stands and pole stands than in mature or old-growth stands, regardless of tree species and site fertility.

Conclusions

Forests are a natural resource of prime importance, and they provide human communities with tangible items such as timber and wildlife and intangible benefits such as scenic beauty, wind reduction, and urban noise abatement. A unique feature of forest production is that its control requires only a small external input. Natural processes exert the greatest control, in the form of the biological diversity that controls the functioning and structure of forested ecosystems. The management and utilization of forest resources in a way that balances human needs with the undisturbed functioning of the forest ecosystem is the key to a form of sustainable forestry which provides ample space for maintaining biodiversity in the world's forests.

The current biodiversity of the boreal forests is a result of long-term evolution and changes in the environment and is thus related to the successional dynamics of the forest ecosystem. The long-term growth and development of tree populations is subject to disturbances due to wind, fire, and attacks by insects and pests, and under boreal conditions in particular, these disturbances cause a cyclic effect in the dynamics of the forest ecosystem by returning it to earlier phases

Table 5 Rarest beetle species with a preference for dead wood presented in order of abundance based on the total number of individuals (Siitonen *et al.*, 1995)

in the succession. For example, a fire that kills old trees provides space for regeneration, enhancement of growth, and the accumulation of mass. Considered over large areas, this means that under natural conditions the boreal forests represent a mosaic of tree stands of varying age from saplings to mature trees and of varying tree species composition. The maximization of growth and timber yield implies that the area of mature or old-growth forests may be smaller than might be desirable in order to conserve the most specialized species.

The forest resources of northern Europe have been utilized intensively during the past 100 years, and this has inevitably had an impact on the current diversity of the forests. The management goal of maximizing the timber yield will inevitably lead to fragmentation of the forests and structural properties which deviate substantially from those arising under the influence of major disturbances. An increasing harvesting rate in terms of regular thinnings, together with a preference for coniferous species and a shorter rotation, will reduce the proportion of deciduous trees and the occurrence of dead and decaying wood. Furthermore, effective fire fighting and measures aimed at increasing the capacity of forests to resist the force of winds and heavy snowfalls will reduce the formation of dead wood and the occurrence of burnt wood, for which many species are specialized.

The previously mentioned tendencies will detract from the conditions which many rare and endangered species need in order to survive, as indicated by the positive correlation

Figure 8 Correlation between the number of saproxylic species and the volume of decaying wood ($r=0.548$, $d.f.=58$, linear scale after logarithmic transformation of the x-axis) and correlation between the number of nonsaproxylic species and the basal area of the tree population ($r=-0.596$, $d.f.=58$, linear scale) (Siitonen *et al.*, 1995).

between the occurrence of these species and the amount of dead wood in the boreal forests. The increasing amount of dead wood probably indicates that there are more specialized microhabitats available under these conditions than in forests with a small amount of dead wood. These highly specialized species seem to be those affected most by the utilization and management of forest resources. However, the occurrence of species other than those confined specifically to dead wood seems to be quite similar regardless of the management history of the forests.

The protection of threatened biota may be based solely on a network of strictly protected areas. Currently, less than 10% of the productive forestland in Finland is strictly protected, and opportunities to increase this within a short time span seem to be limited. Most of the valuable old-growth areas are already protected. Perhaps a better potential for protecting forest biodiversity and threatened species can be found in managed forests, in which the application of silvicultural practices that aim at restoring the natural properties of younger forests can be developed. Natural characteristics can be promoted quite rapidly in young managed forests since such forests are created continuously along with timber harvesting. However, most of the threatened species have highly specialized habitat requirements. By preserving these habitats (key habitats) in forest management, viable populations of these species can be maintained. Consequently, strictly protected areas and biodiversity-oriented management should be regarded as important complementary elements rather than alternatives when planning and developing new forestry practices (Kouki *et al.*, 2000).

Glossary

Agricultural lands, degraded Land currently or formerly used for the cultivation of crops or pasture in which the productivity has been reduced as a result of human actions.

Agricultural lands, prime Land that has the best combination of physical (e.g., moisture status, soil depth, or slope condition) and chemical (e.g., nutrient status and salinity) characteristics for producing food, forage, fiber, and oilseed crops; “food” is used comprehensively to include crops grown for direct human consumption, processed for human consumption, and crops fed to livestock raised for human consumption.

Biodiversity The variety of living organisms considered at all levels, from genetic variants within the same species to the whole range of species and ecological complexes.

Bioenergy Forms of energy that can be extracted from biomass, including biodiesel from fats and oils; bioethanol from sugars, starches, and lignocellulosic material; and bioelectricity and bioheat from the combustion of lignocellulosic material.

Bioethanol Alcohol made from sugar (e.g., sugarcane), starch (e.g., corn grain), or cellulosic (e.g., corn stalks, wheat straw, prairie grasses, and trees) biomass crops that can be used as a biofuel; sugar and starches are converted to ethanol through fermentation, while cellulosic material is

converted via enzymatic hydrolysis or synthesis gas fermentation.

Biofuels Liquid fuels derived from biomass, including biodiesel from fats and oils and bioethanol from sugars, starches, and lignocellulosic material; contemporary or “first-generation” biofuels are derived from sugar, starch, or vegetable oils, whereas emerging “second-generation” biofuels are derived from lignocellulosic materials.

Ecosystem services The benefits that humans derive from ecosystems; for example, timber and crop production, water purification, pest control, pollination, and outdoor recreation.

Feedstock, bioenergy Raw, unprocessed biomass slated for conversion to bioenergy.

Reserves Areas in which the primary management objective is to fully protect native species and ecosystems from direct human modification.

Targeted conservation Strategic land allocation and application of management practices, such as buffers, corridors, constructed wetlands, stepping stones, and reserves, to maintain species populations and ecosystem services in concert with human land use.

Wildlife All nonhuman and nondomesticated animals.

Introduction

In an effort to reduce dependence on fossil fuels and enhance energy security, many countries are mandating the use of bioenergy and heavily investing in its research, development, and production. The European Union, for example, established a directive on the use of renewable energy in 2008 requiring that 20% of the energy consumed by member states be derived from renewable sources with biofuels providing at least 10% of all transportation fuels by 2020 (Commission of the European Communities, 2008). Brazil, China, and the USA have adopted similarly aggressive bioenergy policies in recent years. At first glance, these mandates and the bioenergy production they spark may appear to be a boon for the environment, including wildlife; society is attempting to make much needed shifts from fossil fuels, curb greenhouse-gas emissions, and reduce the impacts of future climate change. Closer scrutiny, however, reveals, that large-scale bioenergy production may constitute an environmental boondoggle (Field *et al.*, 2008; Robertson *et al.*, 2008; Eggers *et al.*, 2009; Tilman *et al.*, 2009), largely because of shifts in land use that are occurring to support it. Ultimately, whether future bioenergy production is helpful or harmful to wildlife depends on society's choice of bioenergy production systems and their configuration at a variety of scales.

The demand for bioenergy feedstocks is already affecting ecosystems around the globe. As of 2010, 8.3 million ha (Mha) of biodiversity-rich tropical lowland forest in Borneo, Peninsular Malaysia, and Sumatra had been converted to oil palm plantations to serve both food and biofuel markets (Koh *et al.*, 2011), with biofuels predominantly driving this expansion in the past decade. Furthermore, Indonesia plans to double its production of oil palm by 2020 to supply the European and East Asian markets (Koh and Ghazoul, 2010). Starting in 1975, Brazil began a large-scale program to produce biofuel from sugarcane to reduce dependency on oil imports. With nearly 7 Mha of agricultural land currently devoted to sugarcane production, Brazil is second only to the USA in bioethanol production, reaching 19 billion liters in 2007 (Monteiro *et al.*, 2010). Expansion of sugarcane production has historically resulted in the direct clearing of the biodiversity-rich Cerrado and Atlantic forest habitats (Silviera *et al.*, 2003), and indirectly to deforestation of Amazonian forests through the displacement of soybean production and pasturelands (Martinelli and Filoso, 2008). In the Brazilian state of Alagoas, sugarcane production has led to the loss of 97% of the original forest cover (Power and de Araujo, 1993). In the USA, national biofuel policies are the partial cause of shifts from a traditional corn-soybean biennial crop rotation to corn-corn-soy rotation or continuous corn cropping and the

conversion of grasslands, including native prairies and other previously untilled areas (Fargione *et al.*, 2009; Babcock and Fabiosa, 2011). Although the exact extent of grassland loss is unknown, the US Department of Agriculture projects the amount of land enrolled in the Conservation Reserve Program, which are predominantly grasslands, will decline from a peak of 14.9 Mha in 2007 to 12.2 Mha in 2013 as these lands are converted to row-crop production (Fargione *et al.*, 2009).

Whether bioenergy will ultimately help or harm wildlife is yet to be determined and, as is often the case regarding human interactions with the environment, the answer will depend on how bioenergy is produced. The environmental impact of bioenergy production is dependent on the chosen production systems – as defined by the types of crop(s) grown, where they are grown, how they are grown, and their transport, storage, and conversion to energy (Dauber *et al.*, 2010). Assessments that holistically consider the environmental tradeoffs associated with different bioenergy production systems are rare. Here the authors review and synthesize global trends, constraints, and opportunities in the development of bioenergy with respect to their impacts on wildlife. In particular, they address the potential for the positive use of bioenergy crops to restore wildlife habitat within agricultural landscapes. Their assessment is based on a combination of theory and literature review. Although the perspective of their synthesis is global in character and representative of all nondomesticated animal species, the information available to support this assessment is limited in breadth, depth, and distribution. Empirical data on wildlife response to bioenergy development have been collected for only a limited number of taxa – mostly birds – and bioenergy crops in Europe, North America, and Southeast Asia (Koh and Wilcove, 2008; Dauber *et al.*, 2010). Although much more research is needed on the impacts of specific bioenergy cropping systems on wildlife across regions of the globe, existing knowledge and established ecological and conservation concepts suggest some guidelines for bioenergy development to be sustainable with respect to wildlife.

Impacts of Changing Land Use – Native Ecosystems

The negative environmental impacts of converting native ecosystems to other uses have been well established within the conservation literature (Sala *et al.*, 2000). Thus, most conservation ecologists agree that bioenergy development that requires conversion of native ecosystems to other land uses, whether directly or indirectly, will result in a net loss for biodiversity and wildlife (Aratrakorn *et al.*, 2006; Bies, 2006; Koh and Wilcove, 2008; Fargione *et al.*, 2009; Edwards *et al.*, 2010). Quantitative studies tracking species richness and abundance with land-use conversion represent only a small number of bioenergy crops, taxa, and regions; results from the few studies that compare native ecosystems and bioenergy systems however report declines for most wildlife species. Specifically:

- Koh and Wilcove (2008) report that bird and butterfly richness are lower – 77% and 83%, respectively – in oil palm plantations compared to primary forest in Peninsular Malaysia and Borneo.

- Edwards *et al.* (2010), also working in Borneo, found imperiled bird species to be 60 times less abundant in forest fragments and 200 times lower in oil palm plantations compared to contiguous native forest.
- Aratrakorn *et al.* (2006) show that conversion of native lowland forest to commercial oil palm and rubber plantations has resulted in a greater than 60% reduction in bird species in Thailand. Furthermore, 94% of bird species of regional conservation concern were only found in native lowland forests.
- Martin and Catterall (2001) record very low avian biodiversity in sugarcane fields relative to residential areas and heathland remnants in eastern Australia.
- Petit *et al.* (1999) show that sugarcane fields supported the lowest numbers of total and migratory bird species compared to 10 other land-cover types in central Panama, with 84% fewer species than lowland forests.
- Riffell *et al.* (2011), in a meta-analysis of eight North American studies, found bird and small mammal diversity and abundance to be consistently lower in short-rotation woody crop (SRWC) plantations relative to native forest cover types.

These types of impacts are not equally distributed across the globe (Hansen *et al.*, 2008) nor limited to the terrestrial environment. Land-use conversion within terrestrial ecosystems tends to severely alter the habitat quality of adjacent aquatic ecosystems through increased sedimentation, turbidity, and water temperatures (Tilman, 1999) and pollution with agricultural chemicals (Relyea, 2005). Furthermore, land-use change acts synergistically with other stressors on ecosystems, such as climate change, altered nutrient cycles, and invasive species, to affect species losses. The authors of the Millennium Ecosystem Assessment predict that these changes may cause global biodiversity declines of 12–16% by 2050 (MEA, 2005). Up to 80% of the species lost – approximately 30,000 species – are expected to come from biodiversity hotspots, locations with exceptionally high concentrations of endemic species such as tropical forests and woodlands, savannas, and warm mixed forests (Bradshaw *et al.*, 2009; MEA, 2005). Accordingly, the clear negative impact of the conversion of native ecosystems suggests that, for bioenergy development to minimize its impacts on wildlife, it should avoid conversion of native ecosystems, especially in biodiversity hotspots.

Further negative environmental and social impacts are associated with the conversion of native ecosystems for bioenergy production, thereby strengthening the support for this assertion. These include:

- reductions in air quality (Hill *et al.*, 2007), pest control (Landis and Werling, 2010), and pollination services (Öckinger and Smith, 2007; Landis and Werling, 2010);
- potential increases in greenhouse-gas emissions (Fargione *et al.*, 2008; Scharlemann and Laurance, 2008); and
- the displacement of existing landholders and/or native peoples (Coutla *et al.*, 2008; Bekunda *et al.*, 2009; Schooneveld *et al.*, 2010).

Whether the displacement of fossil fuels with bioenergy results in a net reduction of greenhouse-gas emissions is particularly noteworthy, because bioenergy is often touted as a

“green” solution and greenhouse-gas emission standards are linked to bioenergy policies in the Europe Union, USA, China, and elsewhere. Although many studies calculate a reduction in greenhouse-gas emissions associated with the combustion of biofuels in comparison to fossil fuels, comprehensive assessments of bioenergy production are not always favorable. For example, *Searchinger et al. (2008)* compute that, when land-use change is factored in, biofuels result in more than doubled greenhouse-gas emissions compared to fossil fuels. *Fargione et al. (2008)* estimate that the conversion of natural ecosystems to food crop-based biofuels causes a net total release of 17–420 times more CO₂ than that annually displaced by using biofuels instead of fossil fuels. Some of the biofuel systems considered in these and similar analyses include sugarcane bioethanol, corn bioethanol, palm biodiesel, and soybean biodiesel. If projections like these are correct, many of the systems being widely implemented today, when coupled with direct or indirect conversion of native ecosystems, actually exacerbate climate change – and its expected impacts on biodiversity and wildlife (*Dawson et al., 2011*) – compared to fossil fuels (*Zah et al., 2007* (as reviewed by *Scharlemann and Laurance, 2008*); *Fargione et al., 2008*; *Lapola et al., 2010*). These results suggest that sustainable bioenergy production should result in overall lower greenhouse-gas emissions compared to the fossil energy. The determination of the greenhouse-gas emissions from a given biofuel requires a full life cycle analysis of direct and indirect impacts.

Native ecosystems are often highly productive; many produce copious amounts of woody and herbaceous biomass, a portion of which could be sustainably harvested as bioenergy feedstocks (*Hoogwijk et al., 2003*; *Perlack et al., 2005*). Indeed, biomass harvested from native ecosystems is the original bioenergy. In the forestry sector, low-value woody material generated in the milling process (e.g., small or deformed material, bark, and sawdust) has long been used to cogenerate heat and power to operate mills, offsetting energy costs, and effectively using what would otherwise be considered a waste product. As energy costs rise, could harvesting, collecting, and hauling additional material from forests savannas, or grasslands become more economically viable? Perhaps not, as woody and herbaceous biomass constitutes food and cover for biodiversity and wildlife when kept in place. In some cases, however, biomass harvest and removal can be helpful in meeting ecological restoration goals. Examples include managing woody encroachment into prairies and savannas where prescribed fire cannot be used because of proximity to buildings or roads; when mechanical thinning of forests is necessary due to decades of fire suppression; or as a means to control an exotic plant that has thoroughly invaded an ecosystem. In these instances, biomass harvests may be a source of revenue that helps to pay for or offset the cost of ecological restoration. Several European nations, Canadian provinces, and US states have articulated specific guidelines as to where, when, and how woody biomass harvests can be done sustainably (*Evans et al., 2010*). Many of the guidelines relate to soil quality, water resources, and aesthetic resources (*Evans et al., 2010*). Guidelines that specifically relate to biodiversity and wildlife include:

- the overall quantity and quality of habitat should be maintained or improved;

- communities of native plants and wildlife should remain intact; and
- the introduction of invasive or nonnative species should be avoided (*Raghu et al., 2006*).

These considerations suggest that, to be sustainable, biomass harvests should not compromise the long-term functioning of native ecosystems.

Impacts of Changing Land Use – Crop and Pasturelands

Social concerns regarding the ethical use of agricultural lands have led to the assertion that bioenergy feedstocks should not displace food production on prime agricultural lands, but rather be grown on other portions of the global land base. For ethical and food security reasons, many people believe agricultural lands should produce food and not fuel (note: the authors use “food” to comprehensively include crops grown for direct human consumption, processed for human consumption, and fed to livestock raised for human consumption). Yet, growing proportions of the world’s cassava, corn, rapeseed oil, palm oil, soybean oil, and sugarcane crops are being routed to bioenergy production streams (*Figure 1*). Additionally, energy crops are now being grown on lands traditionally used to produce food. These shifts are partially responsible for global increases in food prices and food shortages in some countries (*Naylor et al., 2007*; *FAO, 2009*). Undernourishment has been on the rise since the mid-1990s, but rose sharply between 2006 and 2009, peaking at just more than a billion people (*FAO, 2009*). In addition to the human cost, lack of food or rise in food prices can be costly for wildlife. People struggling with poverty sometimes turn to bushmeat as an alternative, though unsustainable, food source when prices of agricultural goods rise (*Bennett, 2002*; *Milner-Gulland and Bennett, 2003*). As with land-use change, the incidence and effects of bushmeat hunting are not uniformly distributed. Bushmeat consumption tends to be disproportionately greater in tropical regions, which support some of the world’s poorest people and two-third of all species (*Milner-Gulland and Bennett, 2003*; *Bradshaw et al., 2009*).

Figure 1 Percent of annual US corn crop used for bioethanol production (USDA ERS, 2011), an example of the increasing use of food crops to generate biofuels.

Furthermore, poverty and undernourishment are correlated with agricultural methods that generate immediate increases in production at the expense of long-term environmental degradation, such as overgrazing, slash-and-burn deforestation, and unsustainable use of soil and water resources (Reynolds and Stafford Smith, 2002).

The food shortages and volatile food prices of recent years may be more of a result of trade distortions, rising energy costs, and a lack of infrastructure than lack of food (Naylor *et al.*, 2007; Heady and Fan, 2008; FAO, 2009; Thurrow and Kilman, 2009). The increase in foreign holdings in major food-importing countries and attempts made by food-exporting countries to mitigate their own food price inflation have played key roles in both facilitating and hindering food distribution (Anderson *et al.*, 2006; Mitchell, 2008; Thurrow and Kilman, 2009). Furthermore, many regions are not as productive as they could be, and food shortages could be overcome by developing the agricultural capacity of these areas, a goal that has proven to be highly elusive for the past 50 years. If resource (e.g., inability to access fertilizer and seeds) and infrastructural (e.g., inability to move food to markets) obstacles to food production and dissemination in sub-Saharan Africa could be overcome, this might alleviate regional hunger with little competition from bioenergy (FAO, 2010). Consequently, if such inefficiencies were overcome and food production were focused on regionally prime agricultural lands, there might be land available to offset a meaningful portion of global energy demand.

Marginal, degraded, or abandoned agricultural lands offer more socially, and thus ecologically, viable options for bioenergy production (Box 1; Field *et al.*, 2008; Robertson *et al.*, 2008; Tilman *et al.*, 2009). A recent assessment by Campbell *et al.* (2008) suggests there is approximately 385–472 Mha of abandoned farmland in the world, which could annually produce 1.4–2.1 billion tons of biomass. If converted to biofuel, this biomass could meet up to 8% of current global energy demand. More efficient and strategic use of the global land base is needed, however, to concomitantly meet food, energy, and environmental pressures (Robertson *et al.*, 2008; Liebman *et al.*, 2011). The next two sections, respectively, review the ability of bioenergy systems to cogenerate these benefits and how these systems may be strategically allocated for this purpose.

Comparison of Bioenergy Systems

Numerous bioenergy systems are being considered for meeting present and future renewable energy needs. These systems vary in terms of their productivity, management, and impacts on wildlife. The impacts of bioenergy systems on the richness and abundance of wildlife species involve reciprocal interactions between crops and wildlife – these interactions influence crop productivity as well as the suitability and environmental implications of bioenergy production (Dale *et al.*, 2010). The authors group and evaluate these systems according to two gradients; the first is associated with the level of agricultural inputs (e.g., chemicals, equipment, seed, and fuel) required to maintain their productivity and the second is the level of plant diversity of composition. Together these

Box 1 Prime, marginal, degraded, and abandoned lands

Prime agricultural lands are those possessing the best combination of characteristics, both physical (e.g., moisture status, soil depth, and slope condition) and chemical (e.g., nutrient status and salinity), for producing crops and livestock. Bioenergy crops are often slated for “marginal,” “degraded,” or “abandoned” lands. Marginal is more variably defined than prime (Dale *et al.*, 2010), but marginal agricultural lands are generally considered to have one or more conditions that make them less conducive to crop or livestock production. These conditions include excessive slopes with high susceptibility for soil erosion when tilled or grazed, excessive wetness, poor soil texture for water and nutrient retention, and shallow depths to bedrock or water table. Degraded lands are current or former crop or pasturelands where the productivity has been semipermanently reduced because of human actions. Common causes of degradation include the removal (i.e., land-cover conversion) or mismanagement (e.g., overgrazing) of natural vegetation; improper agricultural management (e.g., poor tillage or irrigation practices); and industrial activities (e.g., acid rain). According to the Global Assessment of Human-induced Soil Degradation (GLASOD), 15% of the global land base is degraded – an area about twice the size of the USA. Continentally, this breaks down to 23% of Europe, 18% of Asia, almost 17% of Africa, almost 14% of South America, almost 12% of Australasia, and 5% of North America (Oldeman *et al.*, 1991; Figure 2). Abandoned agricultural lands are those once used to grow crops or as pasture, but no longer used because of farmer relocation or degradation due to intensive use. Field *et al.* (2008) estimated the global extent of abandoned agricultural lands to be 386 Mha, or an area comparable to about half the size of Australia, though with a sizable margin of error. Assessing the extent and location of abandoned lands is difficult because of shifting cultivation practices of native peoples, who may periodically use lands that appear to be deserted, for some other reasons.

gradients form four contrasting categories of bioenergy systems: high-input low-diversity (HILD), low-input low-diversity (LILD), high-input high-diversity (HIHD), and low-input high-diversity (LIHD) (Figure 3).

Current food-based crops, so-called first-generation biofuels, are largely composed of HILD systems. Bioethanol and biodiesel are produced from highly productive annual crops rich in sugars, starches, or oils such as corn (*Zea mays* L.), sugarcane (*Saccharum* spp.), oil palm (*Elaeis guineensis*, *Elaeis oleifera*), rapeseed (*Brassica* spp.), and soybean (*Glycine max* (L.) Merr.), among others. First-generation bioenergy crops are most often grown in annual monocultures, which require high levels of fuel, fertilizer, and other petrochemical inputs to maintain their productivity. This reliance on fossil fuels fundamentally compromises the net energy efficiency of conventional bioenergy crops (Kim and Dale, 2005; Hill *et al.*, 2007). For example, Rathke *et al.* (2007), using field experiments comparing corn and soybean production with different tillage treatments and crop rotations, found that crops grown in monocultures had a lower net energy gain than crops grown in rotation. The reason for differences included the higher level of inputs required by monocultures, whereas reduced tillage treatments maximized the energy efficiency from lower fuel costs.

Agricultural practices within HILD systems deliberately maintain ecosystems in a simplified and disturbed state to maximize crop productivity by minimizing resource competition from noncrop plants. These ecosystems provide habitat for only a narrow suite of wildlife, primarily generalist

Figure 2 Global distribution of degraded soils. Data from the Global Assessment of Human-induced Soil Degradation (GLASOD); Oldeman LR, Hakkeling RTA, and Sombroek WG (1991) *World Map of the Status of Human-Induced Soil Degradation*, 2nd edn. Wageningen: ISRIC.

Figure 3 A visual comparison of the composition and structure of example cropping systems that can be used as feedstocks for bioenergy production: (a) corn, (b) hybrid poplar, (c) strip cropping with hybrid poplar, miscanthus, corn, and (d) prairie.

species (Robertson *et al.*, 2011) and sometimes favor crop pests (Landis and Werling, 2010). The simplified vegetative structure of monocultures equates to low habitat complexity, fewer species, and altered foodwebs (Landis and Werling, 2010). Often feedbacks manifest where crop pests favoring the simplified structure trigger greater use of tillage and chemical herbicides or pesticides (Matson *et al.*, 1997), thereby further reducing habitat quality for wildlife. Increased intensification

through agricultural inputs also tends to have nontarget impacts, producing a myriad of stressors on wildlife. For example, biodiversity in aquatic systems can be affected by agricultural practices through: direct lethal effects of pesticides (Relyea, 2005); altered hydrological flows from crop irrigation (Roberts *et al.*, 1997); and nutrient or sediment pollution of freshwater and marine ecosystems, leading to harmful algal blooms and reducing aquatic species richness (Carpenter

Figure 4 Total number of native wildlife species likely to be conserved in native ecosystems vs. different bioenergy cropping systems. Although the actual proportions are hypothetical and dependent on the specific systems under consideration, existing knowledge supports the relative pattern shown.

et al., 1998). In the USA, agricultural practices are the source of impaired water quality on approximately 72% of river miles (EPA, 1994), and are the leading cause of freshwater species declines (Richter *et al.*, 1997). In sum, when considering all potential types of bioenergy systems, HILD systems provide the least benefit to wildlife (Figure 4).

Cellulosic materials left over from the harvest of HILD crops (e.g., corn stover; sugarcane bagasse; rice, wheat, or oat straw) have significant potential as second-generation bioenergy feedstocks. However, these crop residues are important for maintaining soil quality through recycling plant nutrients, storing carbon, and improving water holding capacity. Maintaining residues on site is especially important for reducing soil erosion on sloping and erosion-prone terrain (Blanco-Canqui and Lal 2009). Although indiscriminant removal of crop residues would accelerate soil degradation of prime agricultural lands, removal of a portion of residues could provide a substantial source of bioenergy feedstock while minimizing environmental risks – Nelson (2002) estimated that up to 30% of crop residue can be removed without exceeding tolerable soil erosion levels. Forty percent residue removal could produce 442 billion liters of bioethanol annually, potentially replacing 32% of global gasoline consumption (Kim and Dale, 2005). Beyond the impacts on soil quality,

removal of crop residues affects the wildlife habitat value of bioenergy systems. Residues provide cover and a food source for deer, waterfowl, upland game birds (e.g., turkey, grouse, quail, and pheasant), songbirds, small mammals, and other animals (WHMI, 1999), while providing habitat for insects, an important food source for birds and mammals. For example, Best (1986) found bird species richness was higher in fields with high cover of crop residue (15 species) compared to those with low residue cover (six species). Although crop residues may appear to have some potential as bioenergy feedstocks, the negative impacts on soil resources and the subsequent feedbacks on wildlife further reduce the already meager habitat value of HILD systems.

By comparison, LILD systems benefit a slightly greater number of wildlife species (Figure 4), due to the reduced level of inputs required to maintain productivity. Many, but not all, of these systems are composed of second-generation bioenergy crops; they rely on the conversion of lignocellulosic biomass into bioethanol. Low-input systems are typically composed of herbaceous or woody nonfood perennial species that have low fertilizer requirements because of high nutrient-use efficiency of the plants. Low fertilizer requirements lead to decreased plant-soluble nitrogen concentrations, reducing pathogen, pest insect, and weed populations and thus minimize the need

for harmful herbicide and pesticide inputs (Matson *et al.*, 1997). In a comparison of high-input to low-input systems, Gardiner *et al.* (2010) found that low-input switchgrass and mixed-grass prairie fields both supported a higher diversity of beneficial insect, including several rare or declining invertebrate species, compared to fields of high-input corn. Moreover, a perennial growth habit reduces energy inputs needed for annual tillage and planting, which minimizes soil erosion and leads to reductions in both the inputs needed to maintain productivity and their associated impacts on aquatic biodiversity. Fewer annual field activities in combination with the longer rotation periods of perennial systems result in fewer mechanical disturbances to terrestrial wildlife, such as ground-nesting bird species (Murray *et al.*, 2003).

There is a growing interest in LILD systems because of their increased sustainability and reduced cost of production. Many of these systems can be highly productive with few inputs on both degraded and marginal croplands (Box 1), reducing conflicts between bioenergy and food or fiber production (Somerville *et al.*, 2010). Examples of LILD systems that are being vetted for production on degraded or marginal lands in Europe and North America include perennial grasses such as miscanthus (*Miscanthus giganteus*) and switchgrass (*Panicum virgatum*); SRWC systems such as willow (*Salix* spp.) and poplar (*Populus* spp.); and pine (*Pinus* spp.) species grown in tree plantations. Compared to HILD systems, LILD systems show positive effects on nearly all taxa studied in temperate regions of USA and Europe (Dauber *et al.*, 2010). In an analysis of published studies comparing wildlife responses among native habitats and bioenergy systems, Fletcher *et al.* (2011) found that SRWC plantations affected bird species abundance less negatively than did arable crops. Moreover, the vertical structure found in plantations provides habitat to a broader suite of species, including ground-, canopy-, and cavity-nesting birds (Hanowski *et al.*, 1997). In comparison, row crops provide habitat for only ground-nesting birds that require little cover (Best *et al.*, 1997).

The key to simultaneously boosting the productivity and wildlife habitat benefits of LILD bioenergy systems is matching the suitability of the crop to the regional climate. For example, miscanthus may achieve higher yields of biomass than annual crops like corn, but it requires as much as 60% more water per year. The sustainable production of this feedstock is thus limited to areas with high natural water availability (Hickman *et al.*, 2010), and it is not suitable for arid and semiarid climate zones. Yet, these regions often have abundant degraded land due to unsustainable use in the past; they thus, present vital opportunities for bioenergy production for both economic and environmental benefits. Alternatively, plants in the genus *Agave*, which have traditionally been grown for fiber and alcoholic beverages in Central America, are highly productive and require far less water, making them an attractive feedstock in arid and semiarid regions worldwide (Davis *et al.*, 2011). Likewise, jatropha (*Jatropha curcas* L.), a long-lived tropical tree that is productive on marginal soils, has evoked much interest as a biodiesel feedstock for degraded lands in Africa, Asia, and South America. Jatropha requires few inputs due to its tolerance of drought, low nutrient requirements, and the lack of known pests owing to the toxicity of the leaves and fruit – although toxicity may significantly reduce

jatropha's value for wildlife. Little work has been done that assesses the wildlife habitat value of these and other LILD systems suited for marginal or degraded agricultural lands in dry climates. Although LILD systems provide meager direct benefits to wildlife (Figure 4), other benefits include reduced indirect land-use change resulting from the displacement of food crops, especially in biodiversity hotspots such as tropical ecosystems.

HIHD and LIHD are more wildlife friendly, owing to the greater level of plant diversity contained within them (Figure 3). Wildlife respond positively to the greater habitat complexity associated with more heterogeneous vertical and horizontal structure contained within these systems. High-diversity systems produce bioenergy crops using polycultures where multiple species are grown either in mixtures or mosaics, rather than the production of a single species over large areas as in monocultures. Polycultures can take many different forms, and are considered one of the hallmarks of wildlife-friendly farming (Green *et al.*, 2005). HIHD systems include strip cropping, where rows of different crops are alternated (Figure 3(c)); relay cropping, where a second crop is seeded before the first is harvested; and double cropping, where a second crop is planted after harvest of the first to reduce fallow periods. Advantages of these production methods can include higher overall yields, greater energy efficiency, and reduced inputs compared to HILD systems because the greater biodiversity results in fewer crop pests due to biological pest control (Matson *et al.*, 1997). Examples of HIHD cropping approaches for bioenergy include the incorporation of strips of perennial vegetation, such as hedgerows of fast-growing trees and filter strips of perennial grasses, into areas of annual row crops. For example, Hinsley and Bellamy (2000) showed that enhanced plant diversity and structural heterogeneity associated with increasing area of hedgerows and herbaceous strips on crop field margins is associated with greater biodiversity in the UK. Agroforestry systems in the tropics that consist of multiple canopy layers, such as mature trees, shrubs, and annual crops have been shown to have high biodiversity value for birds, butterflies, and plant species compared to annual crops (Schulze *et al.*, 2004).

HIHD systems for bioenergy have not been widely implemented across agricultural landscapes, so their impacts on wildlife have not been directly assessed; yet, the value of these systems can be predicted based on the observed changes in biodiversity with agricultural intensification during the second half of the twentieth century. In a review of the literature, Benton *et al.* (2003) discussed the effects of agricultural intensification across Europe and North America, and the consequent decline in habitat heterogeneity and biodiversity. For example, Fuller *et al.* (1995) found that 86% of farmland bird species had reduced ranges and 83% had declined in abundance in the UK between 1970 and 1990, as agriculture intensified. The same trends are well documented in North America.

HIHD systems are expected to provide greater benefits to wildlife compared to low-diversity systems; however, LIHD systems trump all others, because of the synergistic positive effects of increased habitat complexity and fewer agricultural inputs (Figures 3 and 4). They result in fewer indirect negative impacts and provide the greatest habitat benefits for wildlife. LIHD systems consist of polycultures of perennial grasses and

forbs, and forestry systems that produce a variety of tree and herbaceous species. Tilman *et al.* (2006) showed that polycultures of prairie species produce large quantities of biomass on marginal or degraded sites in the USA with few inputs. Although similar herbaceous polyculture systems have not been tested elsewhere, marginal and degraded lands in other regions have high potential for LIHD systems that benefit wildlife. In a comparison of the effects of plant diversity in low-input grassland systems, Robertson *et al.* (2011) found bird abundance, especially that of grassland specialists, was higher in LIHD mixed-grass prairie compared to LILD switchgrass stands, highlighting the importance of structural heterogeneity of the habitat patch. In general, the sustainability and habitat value of bioenergy systems, like other agricultural production systems, may be maximized when systems mimic both the structure and function of the native ecosystems they replace (Jackson and Jackson, 2002).

Global, Regional, Landscape, and Local Allocation

All the systems reviewed here – native ecosystems, food systems, and bioenergy systems – can be a part of a sustainable future that includes bioenergy production. In comparison to the status quo, however, these systems need to be implemented more strategically from global to local scales in order to be a boon. Multidimensional planning, when combined with multistakeholder collaboration, offers a powerful pathway for achieving the coproduction of food, fuel, and environmental benefits, including wildlife conservation. Dauber *et al.* (2010) provided a comprehensive assessment, but here the authors provide a few key recommendations for collaborative groups to consider at each scale: global, regional, landscape, and local. Given that any particular system or configuration of systems may benefit some wildlife species and be detrimental to others (Landis and Werling, 2010), they make these recommendations in light of conserving the largest number of wildlife species possible. Defining system-specific wildlife-related objectives is a critical part of the planning process (Groves, 2003).

Because anthropogenic climate change is manifested globally, global scale assessments are needed to determine whether bioenergy production systems actually meet the goal of reduced greenhouse-gas emissions in comparison to fossil fuels (Fargione *et al.*, 2008; Dauber *et al.*, 2010). Although evaluations at finer-scales are necessary for designing and implementing bioenergy production systems specific to regional socioeconomic and environmental context, only assessments global in breadth will reveal whether bioenergy development will be a boon or boondoggle for wildlife. Bioenergy systems that reduce regional greenhouse-gas emissions at the expense of releasing disproportionate amounts of stored carbon through indirect land-use change – for example, through conversion of tropical rainforests, drainage of wetlands, and tillage of unbroken sod – are clearly harmful to wildlife.

Regarding the preservation of native ecosystems, multidimensional assessment, planning, and regulation can be useful for developing and implementing a network of biodiversity reserves to achieve adequate protection of target species and ecosystems (Koh, 2007). Biodiversity reserves are

areas in which the primary management objective is to fully protect existing ecosystems and species populations from direct human modification. Human activities, such as crop production or biomass harvesting, are often prohibited and at least severely restricted within reserves. In 2002, the United Nations Environment Programme's Convention on Biological Diversity adopted a resolution requiring member countries to target at least 10% of each ecological region for placement in reserves. This percentage should be far greater in global biodiversity hotspots (Myers *et al.*, 2000), such as Southeast Asia, Mesoamerica, the Caucasus, and the Horn of Africa. Although delineating biodiversity hotspots is a global matter, reserve networks – which consider the movement of genes, individuals, and species among individual reserves – are generally constructed within regions, which are often defined by political boundaries rather than ecological regions *per se*. Arranging reserves in networks is an essential strategy for adapting to and mitigating the impacts of global climate change, especially given that reserves exist within a matrix of highly altered landscapes (Ellis and Ramankutty, 2008). Although reserves are an important conservation strategy (Noss and Cooperrider, 1994; Groves, 2003), sensible bioenergy policies ought to discourage the conversion of native ecosystems in any location. Yet, native ecosystems may still play a role in bioenergy production if biomass harvests can assist in meeting local restoration goals and do not compromise the long-term functioning of native ecosystem.

Reserves alone however are unlikely to fully protect wildlife in the face of climate change and other stressors (Fischer *et al.*, 2006); they are too few in number and too widely spaced. Consequently, efforts to protect wildlife must be integrated into all land uses. Agricultural landscapes need to be redesigned and to be more hospitable to wildlife by providing more structurally complex habitat than is common within many contemporary agricultural landscapes, which tend to utilize LILD systems, the least desirable for wildlife (Figure 4).

The production of bioenergy feedstocks that do not displace food production on prime agricultural lands is manifested over regional and landscape (1–100 km²) scales. Within regions, some locations are more suited for agricultural production than others, and most existing biodiversity reserves are already relegated to less productive portions of the land base (Noss and Cooperrider, 1994). For example, within the western US, productive river valleys are often under intensive agricultural land use, foothills comprise grazing lands, and the least productive high elevation lands are in reserves (i.e., national parks). Given such spatial arrangements, LIHD bioenergy systems that make use of native species can be targeted to locations surrounding biodiversity reserves; thus, buffering reserves from the impacts of high production agriculture and potentially increasing the core area of wildlife habitat within the reserve while providing a marketable crop. Moreover, all agricultural landscapes have portions that are inherently less productive due to their edaphic conditions; for example, low-lying wet areas, high dry or stony areas, or highly erosive areas along steep slopes. On these portions of the landscape, bioenergy cropping systems could be strategically deployed in schemes that facilitate the coproduction of biomass and environmental benefits as well as serve as buffers, corridors, and stepping stones for wildlife. Buffers protect sensitive habitats,

(a)

(b)

Figure 5 Visualizations of alternative agricultural landscapes that support, food, bioenergy production, and wildlife. (a) Dominated by a HILD corn system in which corn grain is used for both food and to produce bioethanol. In this scenario, the streamside has been set aside and covered with LIHD prairie to protect the stream from the impacts of corn production. This homogenous landscape is expected to support only a small portion of the wildlife species native to the region. (b) Includes a mixture of agricultural crops including HILD corn for food, LIHD switchgrass for cellulosic bioethanol production (foreground), a LIHD reconstructed prairie for forage or cellulosic bioethanol production (streamside), and a LIHD tree and grass intercropping system (back left) for fiber or cellulosic bioethanol production. In this scenario, all sensitive (streamside) and degraded (hillside) agricultural lands have been converted to perennial crops. This heterogeneous landscape is expected to support the majority of wildlife species native to the region.

whereas corridors and stepping stones are designed to facilitate the movement of organisms and genetic material (Fischer *et al.*, 2006). Figure 5 provides a hypothetical example of how targeting might look different from the status quo (Figure 5(a)). A redesigned agricultural landscape might include an LIHD system that is based on a native vegetation type

used in combination with an LIHD system to form a gradient in habitat suitability between an HILD food system and sensitive aquatic habitats (Figure 5(b)). An HIHD system that combines SRWCs and an herbaceous bioenergy crop in an ally cropping system may be targeted to highly erodible lands, providing marketable crops, while also introducing

compositional and structural heterogeneity into an area otherwise dominated by HILD crops (Figure 5(b)). Employing a variety of bioenergy cropping systems across a landscape may allow the bioenergy production systems to mimic both the structure and function of the native ecosystems they replace.

Finally, bioenergy systems also have an important role to play in improving the ecological functioning and wildlife habitat at the local, field scale (<1 km²) on prime agricultural lands. Although the goal at this scale might not be enhanced wildlife habitat per se, biodiversity can provide ecosystem services that are critical for maintaining agricultural productivity, lowering the cost of farming (Higginbotham *et al.*, 1996; Heal and Small, 2002), and enhancing the resilience of agricultural production (Fischer *et al.*, 2006). Ecosystem services that agriculture depends on include nutrient cycling, soil stabilization, pest suppression, and pollination (Kremen *et al.*, 2002; Edwards and Arancon, 2004; Gurr *et al.*, 2004), among others. Moreover, Walk *et al.* (2010) showed that even very small patches of more compositionally and structurally heterogeneous vegetation cover can provide habitat for grassland birds.

Conclusions

Whether bioenergy will help or harm is in the hands of policy makers, land managers, and ultimately the global citizenry. The documented and anticipated changes in wildlife habitat quality, species interactions, and populations suggest the future will be perilous if nothing is done to combat, mitigate, and adapt to climate change (Dawson *et al.*, 2011). Society clearly needs to strive for enhanced energy conservation and the development of renewable energy sources. Although it is widely accepted that bioenergy can and should be a part of the renewable energy portfolio, several important questions regarding its potential contribution remain.

First, how much can bioenergy contribute to the renewable energy portfolio? The science suggests that society needs to lower its expectations with regard to the magnitude of bioenergy's contribution. Factors to be considered in assessments of potential include the overall productivity of the Earth's ecosystems (net primary production), competing demands for biomass (i.e., food, fiber, and habitat), and the efficiency of converting the diffuse calories stored in biomass into concentrated, transportable, and usable energy. Sharlemann (2008) estimated that four times as much land area as is currently used to grow food would be required for fuel crops if all energy for human use was provided through bioenergy. Analysis by Campbell *et al.* (2008) suggested that bioenergy derived from abandoned agricultural lands could maximally offset 8% of current global energy demand (Campbell *et al.*, 2008).

Secondly, how should bioenergy crops be configured on the landscape? The current trajectory of utilizing HILD systems, especially those based on food crops, may not be sustainable at present or over the long term. The land-use changes currently being undertaken to support HILD-based bioenergy have clear negative impacts on wildlife, both through direct habitat degradation or loss, and indirectly by exacerbating climate change (Martinelli and Filoso, 2008; Koh *et al.*, 2011; Searchinger *et al.*, 2008). The high levels of inputs required to

maintain these systems make them less feasible in a resource-limited world (Tilman, 1999; Schiesari and Grillitsch, 2011). Bioenergy based on lignocellulosic materials, especially biomass systems that can be grown with low levels of agricultural inputs, offer more sustainable solutions (Robertson *et al.*, 2008; Tilman *et al.*, 2009; Sommerville *et al.*, 2010). However, implementing these systems requires major technical, economic, cultural, social, and political shifts, including:

- Technical – the development of efficient, scalable methods for converting diverse biomass feedstocks, especially lignocellulosic feedstocks, into concentrated bioenergy (Sommerville *et al.*, 2010; Richard, 2010).
- Economic – the adoption of methods of full cost accounting, which explicitly consider the environmental impacts associated with different forms of energy, including habitat loss and greenhouse-gas emissions (Pretty *et al.*, 2001; Ruhl *et al.*, 2007).
- Cultural – a change in cultural norms such that farmers are compelled to manage for the coproduction of environmental benefits in addition to food and fuel (NRC, 2010; Atwell *et al.*, 2011).
- Social – the redesign of institutions to foster collaboration in meeting targets for producing food, fuel, and environmental benefits over local, landscape, regional, and global scales (NRC, 2010; IEA, 2011).
- Political – an overhaul of existing policies and development of new ones to facilitate the shifts above (Ruhl *et al.*, 2007; NRC, 2010).

In conclusion, despite the paucity of research on wildlife response to bioenergy development (Dauber *et al.*, 2010), the conversion of native systems to bioenergy production is clearly harmful. In contrast, the replacement of HILD crops on non-prime agricultural lands with high-diversity systems could be helpful. Otherwise, whether bioenergy will help or harm wildlife will vary substantially depending on the species under consideration, the land-use bioenergy production is replacing, the bioenergy crops being deployed, and the landscape to regional context the bioenergy crops are grown within. The concepts summarized here provide some principles that could help provide renewable bioenergy while sustaining wildlife over local to global scales, and fostering the substantial technical, economic, cultural, social, and political shifts that can make it so.

Captive Breeding and Reintroduction

Katherine Ralls and Jonathan D Ballou, Smithsonian Conservation Biology Institute, Washington, DC, USA

© 2013 Elsevier Inc. All rights reserved.

This article is revision of the previous edition article by Katherine Ralls and Robin Meadows volume 1, pp 599–607, © 2001, Elsevier Inc.

Glossary

Allele One of two or more alternative forms of a gene.

Founder Wild-caught individual that contributes genetically to the captive population.

Founder genome equivalent Number of equally contributing founders that would have produced the same genetic diversity found in an existing captive population if there had been no random loss of founder alleles.

Genetic drift Variation of allele frequency from one generation to the next that occurs due to chance. Genetic drift leads to the loss of genetic variation in small populations due to the random loss of founder alleles during reproduction.

Heterozygosity Average proportion of loci that are heterozygous (have two different alleles in an individual) in a population.

Mean kinship This value, calculated for every living member of a captive population, is the average kinship between that individual and all members of the population (including itself). Typically, living founders are excluded in the calculation of mean kinships. A population's average mean kinship is the average of the mean kinships of all the individuals in the population.

Reintroduction Releasing individuals of a species into an area where that species no longer occurs in an effort to reestablish a wild population. Reintroduced individuals may be captured from a healthy wild population in another area or may be derived from a captive population if there are no healthy wild populations remaining.

Studbook List of all the living and dead individuals in a captive population that contains information on the mother, father, date of birth, location, and other topics for each individual.

General Aspects of Captive Breeding and Reintroduction Programs

Captive breeding is the only choice for species that are extinct or nearly extinct in the wild. Nearly one-fourth of mammals, 12% of birds, and almost one-third of amphibians are threatened with extinction, according to the International Union for the Conservation of Nature (IUCN) Red list of threatened species. The need for captive breeding will undoubtedly increase as loss and degradation of wildlife habitat continue as a consequence of human population growth. However, captive breeding and reintroduction programs can play only a minor conservation role in comparison to protecting and improving habitat. Owing to limited space, staff, and funds, zoos will not be able to preserve populations of all animal species likely to become extinct in the wild.

The major goal of most captive breeding programs is to develop a self-sustaining captive population. Even if a species is never reintroduced, a successful captive breeding program will supply zoos with animals to exhibit, thereby minimizing the need to collect them from the wild. Captive breeding

programs also have considerable educational value because they are used to inform zoo visitors of the value of conserving biodiversity and to increase public interest in conservation issues. Animals maintained in captive breeding programs also support a variety of research programs.

Several organizations provide help with captive breeding and reintroduction efforts. The International Species Information System (ISIS) has about 825 member institutions in almost 80 countries around the world and maintains a global database on over 10,000 species of captive animals dating back to 1829. ISIS also develops and provides software to maintain and analyze data on captive animals, such as Single Population Analysis and Record Keeping System (SPARKS) and ZIMS (Zoological Information Management System). The World Association of Zoos and Aquariums (WAZA) manages 118 international studbooks for rare or endangered species or subspecies. About 1150 other populations are cooperatively managed at the regional level. In the United States alone, the Association of Zoos and Aquariums (AZA) manages 115 populations through interzoo captive breeding programs known as Species Survival Plans (SSPs). More than 300 other

populations are covered by less formal population management plans. Similar regional programs exist in Europe, Africa, Central America, Australia, and New Zealand. Some species may be maintained in captivity for long periods without the possibility of reintroduction. For example, Pére David's deer and the Mongolian wild horse survived in captivity many decades after their extinctions in the wild before reintroduction began.

The IUCN maintains two international committees that offer help with population management, and reintroduction: the Conservation Breeding Specialist Group and the Reintroduction Specialist Group. In the US, the AZA maintains two similar committees: the Small Population Management Advisory Group and the Reintroduction Advisory Group. Both groups provide guidelines for captive breeding and reintroduction programs and maintain other committees that focus on particular groups of species such as carnivores, primates, or parrots.

Difficulties with Captive Breeding and Reintroduction Programs

Not all species breed well in captivity. The species that are easiest to breed in captivity are those that have management requirements similar to those for domestic animals or for other species with which zoos have had considerable experience. For example, zoos suddenly faced with the challenge of breeding California condors experienced little difficulty because they had been breeding Andean condors for many years. However, species with which zoos have had little prior experience may breed very poorly at first until zoos develop appropriate husbandry techniques. Thus, because husbandry techniques tend to be species specific, new captive breeding programs often require substantial research programs on behavior, reproductive biology, nutrition, genetics, or disease. Research on closely related species is also often helpful.

Poor reproduction in captivity is often due to behavioral problems caused by inadequate husbandry techniques. Because different zoos often have different degrees of success in breeding a particular species, important insights can often be gained by comparing the behavior and reproductive success of individuals kept under different conditions at different zoos. More invasive research work can also make important contributions. For example, studies on black-footed ferret reproductive biology have improved captive breeding success for this species. *Asa et al. (2011)* have suggested that allowing individuals to mate with preferred partners might improve reproductive success. If true, it will be important to develop ways to allow mate choice without compromising genetic goals for captive populations.

A captive population's risk of extinction is increased by inbreeding and loss of genetic variation, and inbred animals with little genetic variation are less likely to survive when reintroduced to the wild than more outbred individuals. However, both inbreeding and loss of genetic variation are unavoidable in small, closed populations because all individuals in the population eventually become related to each other. Captive populations are routinely managed to minimize inbreeding and loss of genetic variation. Another threat

to captive populations is that selective pressures in captive habitats are different than those in wild habitats; thus captive populations tend to adapt to captivity, which can make it more difficult to re-establish a population in the wild. Genetic management can reduce but not prevent adaptation to captivity. Thus, it is advisable to minimize the number of generations in captivity before animals are reintroduced when possible.

Learned behavioral traits can degenerate in captivity even more rapidly than genetic diversity. Traits that may degenerate in the captive environment include foraging skills, detection and avoidance of predators, and fear of humans. When captive-bred and wild-born individuals have been experimentally released in the same location, the captive-bred individuals have tended to survive for shorter periods due to lack of appropriate behaviors. Behavioral problems tend to be species-specific and research on how to minimize these problems and thus maximize survival of the reintroduced individuals is often needed when starting a reintroduction program.

Genetic and Demographic Management of Captive Populations

In contrast to husbandry of captive animals and reintroduction techniques, genetic and demographic management methods are similar for all captive populations (*Ralls and Ballou, 1992; Ballou et al., 2010; Frankham et al., 2010*). Genetic and demographic management of captive populations focuses on maintaining genetic diversity in order to minimize undesirable genetic changes due to selection in the captive environment, avoid deleterious effects of inbreeding depression, and maintain future options for genetic management.

Ideally, the first step in the development of a captive breeding is agreement among all concerned parties, such as agency personnel, nongovernmental conservation groups, and outside scientific advisers that such a program would benefit a particular species. Once in place, captive breeding programs have three phases. In the founding phase, the captive population is started. In the growth phase, the population rapidly increases to the final "target" population size specified by its managers. In the carrying capacity phase, the population is maintained at its target size and excess individuals may be reintroduced into the wild (**Figure 1**). Management concerns change as the captive population progresses through these phases.

The main management concerns during the founding phase are removing individuals for the captive population with minimal impact on the wild population, acquiring enough founders from the wild to achieve genetic goals, getting the species to breed reliably in captivity, and setting general goals and plans for the captive population. Ways to capture animals for the captive population with minimal impact on the wild population include removing eggs from nests, using orphaned or injured animals, and capturing dispersing juveniles. Many birds (e.g., condors) will usually lay another egg to replace an egg that has been removed, and dispersing juvenile mammals often have high mortality rates

in the wild. If the species is one that zoos do not know how to breed reliably in captivity, it is best to solve husbandry problems with only a few wild individuals or even animals of a closely related species.

Genetic goals for a captive population are usually specified in terms of the proportion of genetic variation (measured as heterozygosity) to be maintained for a specified time. A common goal is to maintain 90% of the genetic diversity of the source population for 100 years. However, some programs use other time frames. For example, the Guam rail and black-footed ferret programs are using the goal of “90% for 50 years” because of the short generation times for these species (Table 1) and plans for the rapid establishment of several wild populations.

Once a genetic goal has been set, population genetics theory enables calculation of the number of founders needed for the captive population (the number of wild animals that must be captured and successfully bred) and the target

Figure 1 The development of a captive breeding and reintroduction program from the founding to the capacity phase.

population size (the number of individuals that the population needs to grow to achieve its genetic goals). Planning to retain a higher proportion of genetic variation usually increases the target population size. Increasing the number of founders reduces the size of the target population needed to reach a particular goal. Twenty to thirty unrelated individuals are generally a sufficient number of founders. Unfortunately, many existing captive breeding programs were begun after it was already too late to acquire this many founders. For example, the ferret population had only 10 founders. If it had been possible to obtain 25 founders, the target population size could have been reduced from 500 to 200 individuals. Although a small number of founders reduces the probability that a captive breeding program will be successful, it does not doom it to failure. Thus, the lack of an ideal number of founders does not justify abandoning or failing to initiate a captive breeding program.

The target population size also depends on the rate of species reproduction and generation length. A smaller target population will be required to reach the genetic goal if the species can grow more rapidly each generation or if it has a long generation time (because genetic variation is lost due to genetic drift each time individuals reproduce). The target population size may also be limited by practical considerations, such as the number of spaces available in zoos. Fewer zoos may be willing to participate in the program if the species is not attractive as an exhibit. Thus, the target population size may be a compromise between genetic and demographic factors and the limited resources available.

Once husbandry problems have been solved and the species is breeding well in captivity, the rest of the founders should be obtained as soon as possible. Unfortunately, the number of animals that must be captured from the wild is usually greater than the number of founders needed. Wild-caught animals may be related or fail to breed, or their descendants may fail to reproduce. For example, although 25 wild black-footed ferrets were captured, some died of distemper, some were known to be parents and offspring, and some failed to reproduce. Although ideally each founder would contribute an equal number of offspring to the captive

Table 1 The goals and number of founders of captive breeding programs with reintroduction components^a

	<i>Species</i>			
	<i>California condor^b</i>	<i>Black-footed ferret</i>	<i>Guam rail</i>	<i>Golden lion tamarin</i>
Heterozygosity goal (%)	90	90	90	90
Length of program (years)	200	50	50	200
Number of generations	10	20	22	33
Target population size	150	500	150	550
Number of wild-caught	14	18	21	69 ^e
Number of contributing founders ^c	14	10	13	45
Founder genome equivalents ^d	8	5	5	12

^aSpecies are listed in order of increasing number of generations in the program length (reproduced from Ralls and Ballou, 1992).

^bHeterozygosity goal and program length have not been officially adopted by program managers; target population size is the minimum size of the captive population (which, with the two reintroduced populations in California and Arizona, should total no less than 450–500). Other data derived from Mace (2010).

^cFounders with currently living descendants.

^dThe number of theoretically ideal founders taking into consideration loss of genetic diversity in the current captive population (Lacy, 1989).

^eIncludes the number of wild-caught tamarins acquired after the captive program was initiated in 1981 in addition to the number of founders and wild-caught individuals alive at the initiation of the program.

population, those ferrets that did reproduce did so unequally, skewing their genetic contributions to the captive population. Ultimately, the ferret population was founded by the theoretical genetic equivalent of only five ferrets; that is, five founder genome equivalents.

Management efforts during the growth phase center on getting the population to increase as rapidly as possible. Rapid growth has two benefits: it increases the captive population's chances of survival and it retains as much of the founders' genetic diversity as possible. Small captive populations are at higher risk of extinction due to many factors, including random demographic events (such as a succession of male births), inbreeding depression, and unpredictable events that can kill numerous individuals such as diseases, fires, hurricanes, and other catastrophes.

The standard SSP breeding strategy used in the US is designed to maximize the retention of genetic diversity. This is accomplished by minimizing mean kinship among the members of the captive population. Breeding pairs are formed based on mean kinship, beginning with the individuals with lowest mean kinships, until the desired number of pairs is attained. Efforts are also made to avoid mating closely related individuals when forming new pairs. During the growth phase, this strategy is modified slightly to choose new pairs to minimize mean kinship as much as possible but breed all individuals in the population.

Species living in groups, where individuals cannot be individually managed (i.e., fish in tanks, flocks of birds, some antelope herds), need to be managed differently. Here genetic

management focuses on maintaining multiple groups of individuals, periodically transferring individuals between groups, and for some species, restricting the number of offspring any one individual can have (e.g., limiting the tenure of herd sires in an antelope herd).

Although managers attempt to minimize mean kinship and inbreeding during the growth phase, rapid population growth takes priority over genetic concerns, particularly when the population is very small and the risk of extinction outweighs the risk of a few less-than-ideal matings. For instance, if a female rejects the genetically ideal mate, she may be allowed to mate with another male she prefers.

At some point during the growth phase, the captive population usually is divided into subpopulations housed in different breeding facilities. This reduces the risk that a catastrophe such as disease or fire will decimate the entire captive population. To ensure that each subpopulation is as genetically diverse as possible, each should have individuals descended from each of the founders.

Once the population has reached the target size, relatively few offspring may be needed each year to maintain it at that level. Thus, genetic concerns become more important as managers need to determine exactly which individuals to breed in the population.

The number of offspring needed to maintain the captive population can be calculated by standard demographic techniques. Any "extra" offspring can be used for reintroduction. If there are more offspring than are needed for reintroduction, managers can prevent some adults from breeding either by

Table 2 The elements of a successful captive breeding and reintroduction program

Captive population

- Ongoing research in behavior, genetics, physiology, nutrition, reproduction, and pathology
- Genetic and demographic management of the population
- Self-sustaining viable captive population
- Sufficient size to remove animals for reintroduction without impacting the viability of the captive population

Field studies

- Regular censuses of the size, distribution, and genetics of the wild population
- Behavioral ecology studies (home range size, movements, habitat preferences, social organizations, mating system, feeding, and antipredator adaptations)
- Locating existing suitable habitat containing critical resources for reintroduction

Habitat preservation and management

- Protection of habitat from degradation and exploitation
- Restoration and management of degraded habitats
- Increase in or maintenance of the number of preservation areas

Conservation education for long-term support

- Professional training through academic studies, workshops, internships, courses, and fellowships
- Determining the most appropriate public relations and educational strategies through surveys
- Public relations educational efforts using appropriate mass media (e.g., television, radio, magazines, and newspapers)
- Local community education, both formal and informal

Preparation and reintroductions of animals

- Choice of candidates and assessment of their characters for retrospective correlation with postrelease survival
- Training in survival techniques, including foraging and feeding, antipredator tactics, locomotion, and orientation
- Adaption to local conditions at release site (food, climate and temperature, and disease)
- Release and long-term monitoring to evaluate causes of death and basis for survival

using contraceptives or by housing them individually or in same sex groups.

There are two general strategies for producing the individuals to be reintroduced. If the date of a reintroduction effort can be scheduled well in advance and the species has a predictable breeding pattern (such as breeding once a year during the spring), males and females can be paired up for the specific purpose of producing excess young for that particular reintroduction. However, if the date of a reintroduction effort is difficult to predict in advance (this may occur due to difficulties with funding or permits), animals for reintroduction can be selected from the existing population and breeding pairs can be set up to replace the reintroduced individuals.

In the early stages of a reintroduction program, reintroduction techniques are still being refined and mortality may be high. Thus, initially the most genetically expendable individuals are usually released. Later, emphasis will gradually shift to choosing individuals that are not closely related to the individuals already present in the wild population. This maximizes the genetic diversity of the wild population. The final genetic goal is to make the wild population as genetically diverse as the captive population.

Reintroducing Captive-Bred Animals to the Wild

Ideally, the goals of all captive breeding plans would include reintroduction back to the wild. However, some species may be impossible to reintroduce due to lack of habitat or other problems. Furthermore, some species will be easier to

reintroduce than others. The elements of a successful reintroduction program are shown in **Table 2**. These elements include research on both the captive and wild populations, habitat preservation and management, conservation education to ensure long-term support of the program, and careful management and monitoring of the reintroduced individuals (Serena, 1995; Seddon *et al.*, 2007; Griffiths and Pavajeau, 2008; Earnhardt, 2010). The IUCN and AZA have developed guidelines that discuss the biological, socioeconomic, and legal requirements for successful reintroduction.

Most important, reintroduction is a realistic goal only when habitat protection is an integral part of the species' overall conservation plan. A species should not be reintroduced unless the factors that led to its decline in the wild have been identified and eliminated – or at least greatly reduced – and suitable legally protected habitat exists. In addition, the release site should be within the species' historic range. Occasionally, however, a species must be "reintroduced" into areas of suitable habitat outside of its historic range. For example, the Guam rail was reintroduced to the nearby island of Rota because the non-native brown tree snake, which led to the bird's extinction in the wild, has invaded its entire historic range on Guam. Similarly, a variety of species, including birds, reptiles, and invertebrates, from New Zealand and Australia are being reintroduced to offshore islands that are free of the non-native predators that led to their extinction on the mainland.

There are many other factors to consider when reintroducing captive-bred individuals. For instance, the release of captive-bred animals can spread diseases to an existing wild

Table 3 Checklist for deciding whether or not appropriate conditions exist for beginning a reintroduction program applied to three species of lion tamarins

	<i>Lion Tamarin Species</i>		
	<i>Golden</i>	<i>Golden-headed</i>	<i>Black</i>
<i>Condition of species</i>			
1. Need to augment wild population	Yes	No	Yes(?)
2. Available stock	Yes	Yes	No
3. No jeopardy to wild population	?	?	?
<i>Environmental conditions</i>			
4. Causes of decline removed	?	No	No
5. Sufficient protected habitat	Yes(?)	No	Yes
6. Unsaturated habitat	Yes	Yes(?)	?
<i>Biopolitical conditions</i>			
7. No negative impact for locals	No	?	?
8. Community support exists	5	2	4
9. GOs/NGOs supportive/involved	Yes	Yes	Yes
10. Conformity with all laws/regulations	Yes	?	?
<i>Biological and other resources</i>			
11. Reintroduction technology known/in development	4	3	3
12. Knowledge of species' biology	5	1.5	3
13. Sufficient resources exist for program	Yes	No	No
<i>Recommended reintroduction/translocation?</i>	Yes	No	No

Some conditions were rated on a numerical scale from 0 = worst to 5 = best.

population or disrupt its social organization. Thus, it is advisable to screen captive-bred individuals for diseases prior to release and to release them in habitat that has no wild individuals.

When reintroduced to the wild, captive-bred individuals are likely to suffer high mortality rates due to inappropriate behavior. For example, they may have difficulty finding enough food or fail to avoid predators. It has proven very difficult to help orphaned sea otter pups raised in captivity develop appropriate foraging skills and teach them to avoid humans. Captive-bred condors develop appropriate foraging skills fairly easily but often fail to avoid humans and human structures. Substantial research programs are often needed to develop husbandry and reintroduction techniques that will promote behaviors needed for survival in the wild.

The conditions under which captive-bred individuals are raised can be critical. The development of appropriate survival skills may require a skilled parent or a particular stimulus at some critical period during development. For example, adult ferrets prefer eating whatever they were fed when they were 2 or 3 months old, which is when ferrets develop their permanent teeth. Therefore, at the age of 2 or 3 months, captive ferrets should be fed prairie dogs, their exclusive prey in the wild. Methods of reintroduction may also require research. For example, should the animals be released as social groups or as individuals? Should they be fed after they are released and, if so, for how long? The answers to such questions depend on the particular species being reintroduced. Reintroduction programs using captive-bred individuals are usually expensive, lengthy, complex, and difficult. Thus, the decision to begin such a program should not be made lightly. A short checklist of the major factors should be considered when deciding whether or not to reintroduce a species is illustrated in [Table 3](#) with respect to three species of lion tamarins. Answers to the questions in the checklist indicate that reintroduction is appropriate for golden lion tamarins but not the two other species because the causes of their decline have not been eliminated and funds to support a reintroduction program are not available.

There are no generally accepted guidelines for declaring the success of a reintroduction effort. Beck and colleagues suggested two possible criteria: if 500 wild individuals survive without human support or if a formal population viability analysis predicts that the population would be selfsustaining ([Beck et al., 1994](#)). Successful captive breeding and reintroduction programs require sustained long-term,

adequately funded efforts. Research can solve many problems involved in successfully breeding a species in captivity and reintroducing it to the wild. However, the ultimate success of many programs, such as that for the black-footed ferret, will depend on whether or not we are able to preserve enough suitable habitat to sustain viable wild populations of the species.

Captive Breeding and the Evolutionarily Significant Unit

Robin S Waples, NOAA Fisheries, Seattle, WA, USA

Published by Elsevier Inc.

Glossary

Captive breeding Human-mediated breeding and rearing of wildlife under controlled conditions.

Distinct population segment A subspecific unit that can be afforded legal protection under the US Endangered Species Act.

Ecological exchangeability Occurs if individuals can be moved interchangeably among populations and perform similar ecological functions.

Evolutionary legacy Genetic resources that are the product of past evolutionary events and also represent the raw material for future evolution.

Hatchery A facility in which aquatic species are spawned and resulting juvenile progeny are reared for at least part of their life cycle.

Monophyly A monophyletic unit (one that includes a common ancestor and all of its descendants) is said to exhibit monophyly.

mtDNA A small, maternally inherited molecule of DNA found only in the mitochondria.

Pacific salmon Any of several species in the genus *Oncorhynchus* that always die after spawning (and hence are semelparous). Five Pacific salmon species occur in North America: Chinook, coho, sockeye, chum, and pink. Western trouts in the genus *Oncorhynchus* are closely related to Pacific salmon; however, like the Atlantic salmon (*Salmo salar*), these species can spawn in more than 1 year. Steelhead, the anadromous form of rainbow trout (*O. mykiss*), is also discussed in this paper.

A Variety of Evolutionarily Significant Unit (ESU) Concepts

Those interested in applied conservation biology face a daunting task, given that biological diversity occurs along a continuum from individuals to populations, species and higher taxa, together with all the interactions among groups of organisms that characterize functioning ecosystems. Inevitably, triage is necessary to select from this overwhelming array of biodiversity those segments that should be the focus of conservation efforts. The concept of ESUs can help guide this process of triage. Originally intended as a means of helping to determine how to apportion the limited resources available in zoos for captive breeding (Ryder, 1986), the ESU concept has subsequently been applied much more broadly to the general problem of defining units for conservation.

Although ESUs have caught the attention of conservation biologists and evolutionary biologists, a consensus has not emerged regarding how best to identify them (for a review, see Fraser and Bernatchez, 2001). The original description of the ESU concept (Ryder, 1986) provided few details regarding implementation but did identify a broad range of types of information that should be considered, including natural history, morphology, distribution, and genetics. The first practical applications used the framework developed by Waples (1991, 2006), which has been used to guide conservation of Pacific salmon (*Oncorhynchus* spp.) under the US Endangered Species Act (ESA). Under this framework, to be considered an ESU a population or group of populations must meet two criteria: (1) it must be substantially isolated reproductively from other populations of the species and (2) it must make a substantial contribution to the evolutionary legacy of the species as a whole. Tagging data and inferences about migration based on neutral genetic markers are

important sources of data for evaluating degree of reproductive isolation. The second criterion focuses on adaptive genetic differences and is trickier to evaluate because typically one has to rely on proxies (e.g., information on genetically based life history traits (which can also be influenced by environmental factors) and on physical and biotic features of the habitat (which collectively determine the pattern of natural selection experienced by the population)).

Quite a different approach was proposed by Moritz (1994), who wanted to direct conservation attention to lineages that had been isolated for long periods of time. Accordingly, he proposed that ESUs must exhibit reciprocal monophyly of mitochondrial DNA – that is, based on its mtDNA genotype, every individual within an ESU must be more closely related to other individuals within the ESU than to any individual outside the ESU. Even after populations become isolated, it can take a great deal of time before reciprocal monophyly is achieved, so this approach is effective in identifying divergent, isolated lineages; it is also easy to apply and has been widely used for a variety of organisms. However, it is a stringent criterion for assessing intraspecific diversity (many full species do not show monophyly for mtDNA), is less applicable to plants and other taxa than it is to animals, and makes no attempt to assess the importance of adaptive differences. In response to this latter (perceived) limitation, Crandall *et al.* (2000) proposed a framework based on genetic and ecological exchangeability. Rather than specifying a fixed criterion for identifying ESUs, their framework attempts to identify some important places along the spectrum of population differentiation. Those populations that are less exchangeable (replaceable) are stronger candidates to be ESUs and could be afforded higher conservation priority. Populations that are not ecologically exchangeable are likely to harbor important local adaptations. Unfortunately, ecological exchangeability is

difficult to assess directly, so in most cases inferences must be drawn from other types of information.

Although a single, unified theory of ESUs has not emerged, some common elements can be identified. First, two major axes of biodiversity should be considered: one related to isolation, and one related to adaptation. The published ESU concepts differ in the relative importance they accord to each of these axes, as well as in specifics of how to evaluate each axis. Second, there is a general recognition that it is not enough to identify (and hopefully conserve) populations and groups of populations (i.e., the pattern that is the product of evolution); rather, it is important also to conserve ecological and evolutionary processes that provide the context for promoting local adaptations, heterogeneity, and viable populations (Moritz, 2002).

Captive Breeding

Captive breeding has become an important component of conservation planning for many endangered species (see review by Ralls and Meadows, print version of the *Encyclopedia of Biodiversity*), and captive breeding programs now exist for a wide range of species. It is generally recognized that captive breeding is most effective when integrated into a comprehensive conservation program that addresses problems faced by the species in the wild (most frequently, these problems involve loss or degradation of habitat). Ralls and Meadows describe three phases of a typical captive breeding program: (1) a founding phase, during which managers attempt to balance the need to use an adequate number of founders against risks such collections would pose to the remaining wild population; (2) a growth phase, during which captive abundance is increased as fast as reasonably possible; and (3) a capacity phase, during which the captive population has approached carrying capacity and a portion can be used for reintroduction into the wild.

The goals of captive breeding programs are diverse and often include both short- and long-term objectives. The short-term objective is generally to maintain the gene pool, with minimal losses of diversity, while efforts are made to address the root causes for the species' decline. Although a new species often presents unexpected challenges for successful husbandry, the empirical record demonstrates that many captive breeding programs have been successful in achieving their short-term objectives, over periods of a few decades. Ideally, the long-term goal includes re-establishing a self-sustaining population in the wild. This is much more difficult to achieve, for two major reasons. For some species there are no realistic prospects for securing sufficient habitat to support reintroductions in the foreseeable future; therefore, simply maintaining the gene pool in captivity becomes a long-term objective. Second, even when habitat conditions are more favorable for reintroduction attempts, they might not be successful. Environments experienced by captive populations differ dramatically from those experienced in the wild, and as a consequence captive populations are subject to behavioral and genetic changes (domestication) that can compromise their ability to survive and reproduce in the wild. Although encouraging progress is being made to resolve some of these complications, too few empirical examples exist

to provide a sound basis for predicting the likelihood of long-term success of any given reintroduction effort.

Captive breeding of fish and other aquatic populations has been conducted for thousands of years. Although some recent captive programs have conservation objectives, historically these efforts were designed either to provide a source of food (as in domesticated livestock) or to enhance harvest opportunities. To achieve the latter objective, it is necessary to release captively reared individuals into the wild. This unusual feature of aquatic species – that large numbers of captive individuals are released into the wild where they can interact with wild populations (Lorenzen *et al.*, 2010) – presents some unusual challenges in defining conservation units.

An Example from Pacific Salmon

Pacific salmon have an unusual life cycle (Figure 1). Adults spawn in fresh water; the eggs incubate buried in gravel in streams or lakes; juveniles spend a few days to a year or more in fresh water before migrating to sea as smolts; subadults grow rapidly for 1 or more years in the ocean before maturing and returning to fresh water (generally to their natal stream) to spawn and die.

Major anthropogenic changes to salmon habitats in the Pacific Northwest and California started before the US Civil War and have continued to the present day. As a result of a series of status evaluations conducted in the 1990s, about half of the remaining salmon populations in the contiguous US are now listed as threatened or endangered “species” under the US ESA. These listings have taken advantage of a provision of the ESA that allows listing of “distinct population segments” (DPSs) of vertebrates – a provision that has been used to list US populations of alligators, grizzly bears, and bald eagles, among others. The ESU framework developed by Waples (1991) has guided the Pacific salmon listing determinations; groups of populations have been considered to be DPSs if they met the two criteria to be ESUs (reproductive isolation and

Figure 1 Life cycle of Pacific salmon. Solid lines with arrows indicate the life cycle in the wild; dashed lines with arrows and shaded polygon indicate life cycle in captivity. Most Pacific salmon hatcheries release juveniles near the hatchery when they are ready to undergo their downstream migration to the sea; some hatcheries transport juveniles and release them near tidewater.

contribution to evolutionary legacy). Most Pacific salmon ESUs include quite a few (typically 20–30) separate populations or stocks that differ somewhat in ecology, life history, and genetics, but differences among populations within ESUs are typically much less than those among ESUs.

Captive propagation also has a long history with Pacific salmon; the first salmon hatcheries on the West Coast were built in the 1870s. By far the most common form of propagation is known as sea ranching, where adults are spawned in captivity and their progeny reared as juveniles until they are released into the wild. Today, hundreds of facilities around the Pacific Rim release several billion juvenile Pacific salmon into the wild each year. Historically, the objective of most of these programs has been to provide more adult salmon for harvest than can be produced by wild populations alone. More recently, some hatchery programs have developed conservation goals, and some have dual goals of fishery enhancement and conservation. The scale of these programs has raised considerable concern, as well as considerable uncertainty, about long-term effects on natural populations (Fraser, 2008; Araki and Schmid, 2009).

As natural salmon populations became listed as threatened or endangered, it became important to determine what, if any, legal protections hatchery fish should receive under the ESA. To address this need, NMFS developed a two-step process. In the first step, biologists reviewed stock histories and other pertinent information for each hatchery population associated with a listed salmon ESU and determined which hatchery populations are part of the ESU. **Figure 2** illustrates how ESU determinations were made for hatchery populations using the lineage-based ESU framework of [Waples \(1991\)](#). Stock histories and genetic analyses were used to determine which population/ESU the hatchery population in question was derived from, and then all available information was considered to determine whether the hatchery population had diverged so much from its natural progenitors that it no longer should be considered part of the same ESU. In most cases, absent information for substantial divergence or mixing with other populations, hatchery populations recently derived from a natural population were considered to be part of the ESU. The second step involved an administrative decision whether to list (and therefore afford legal protection to) the hatchery populations that are part of listed ESUs. In general, such populations were not listed because doing so would provide little or no additional conservation benefit but would create considerable administrative and bureaucratic burdens for the general public as well as the agency. Exceptions were made for hatchery populations considered “essential” for recovery; such populations were listed to ensure that the remnant gene pool received the necessary legal protections to ensure its persistence. A key element of this approach was that hatchery populations that were included in the ESU were only viewed as potential contributors to eventual recovery and delisting; status evaluations of (and recovery planning for) the listed ESUs focused on demonstrating that the natural populations are self-sustaining without relying on continual influx of hatchery individuals ([McElhany et al., 2000](#)).

The legal framework for this approach was called into question by a federal court ruling (*Alsea Valley Alliance v. Evans*, 2001) that held that the smallest unit that can be listed under

Figure 2 A lineage-based approach for evaluating evolutionary relationships between wild (black circles) and hatchery (open circles) populations in two ESUs. In ESU 1, hatchery population C' is recently derived from wild population C and has diverged relatively little so is still considered to be part of the ESU. Hatchery population D' was derived from wild population D in the more distant past and/or has undergone so much genetic change due to domestication or stock mixing that it is no longer considered part of the ESU. In ESU 2, the relationship between populations Z and Z' is similar to that between C and C' in ESU 1, so hatchery population Z' is included in ESU 2. However, if fish from Z' are released into the geographic area of ESU 1, they do not become part of ESU 1, even if they successfully reproduce there, because they are from a different lineage.

the ESA is a “DPS” (which, for salmon, is legally equivalent to an ESU). A consequence of this ruling is that the agency must either list or not list an entire ESU and all its component members, whether hatchery or wild. This ruling caused considerable controversy and concern because the agency was seemingly faced with a dilemma: either (1) include in the salmon listings millions of hatchery produced fish, which would greatly (and unnecessarily) increase the regulatory burden on the agency and the public; or (2) forego legal protection for entire ESUs whose wild populations were at serious risk. An influential paper ([Myers et al., 2004](#)) concluded that hatchery fish should categorically be excluded from ESUs but provided few details about how this might be accomplished in a biologically sound framework. A subsequent workshop considered this topic in detail and produced a report ([Hey et al., 2005](#)) that outlines a novel approach for considering ESUs and captive breeding.

Two Ways of Thinking about Captive Populations and ESUs

The salmon ESU framework (as well as all other published ESU concepts) begin by identifying evolutionary lineages – groups of individuals that have a shared ancestry. To merit separate ESU consideration, different lineages must be isolated

strongly enough and for enough time to allow evolutionarily important differences to accrue, though a process of selection and local adaptation, random genetic drift, or (more likely) a combination of the two processes. Because considerable time is required for different units to become ESUs, it follows that loss of “evolutionary significance” or “evolutionary legacy” will also, in general, be a gradual process. Of course, the process of genetic change can be accelerated by anthropogenic factors, particularly in captive breeding programs where selective pressures are very different from those experienced in the wild. Nevertheless, under the published ESU frameworks it would be difficult to conclude that a recently derived hatchery population, operated according to conservation guidelines, had diverged so much that it was no longer part of the ESU it was derived from. This would be especially true for fully integrated hatchery programs (in which wild fish are taken into the hatchery every generation to spawn and hatchery produced fish are allowed to spawn naturally every year), since in this case there is no separate hatchery population but instead a single hatchery-wild system. Within such a hatchery-wild system, all individuals share a common evolutionary lineage, differing at most by one or a few generations in the number of hatchery versus wild ancestors each has.

Hey *et al.* (2005) concluded that considering evolutionary lineages is a necessary but not always sufficient condition for defining conservation units. They argued that, in some cases at least, the current ecological context can be more important than evolutionary lineage in determining conservation status. A salmon hatchery (or any captive breeding program) represents a very different ecological context from that experienced in the wild. As illustrated in Figure 1, in a typical salmon hatchery adults are collected from the wild and spawned in captivity, where their progeny are reared until they are ready to smolt (i.e., undergo the physiological transition to seawater). In some cases, to minimize mortality through anthropogenically altered freshwater migration corridors, hatchery smolts are transported and released close to tidewater. This radically different ecological context, in turn, means that captive individuals experience a profoundly different suite of evolutionary processes during their life cycle. Not only does the hatchery actively intervene in the process of reproduction, it also serves as a substitute for most or all of the freshwater life cycle of the juvenile salmon. In the view of Hey *et al.* (2005), removing wild individuals from their natural ecological context disrupts the dynamic processes that have shaped evolution of the ESU, and so captive-origin individuals can be considered not to be part of the ESU. Under the framework proposed by Hey *et al.* (2005), determining ESU membership is as easy as determining whether an individual was reared for part of its life cycle in a hatchery (hence, all the hatchery populations in Figure 2 would be considered not to be part of the ESUs). Importantly, this conclusion based on current ecological context is not a judgment about the value of hatchery fish or their potential for use in recovery of depressed wild populations. Instead, it is a statement about the role they are currently playing in their ecosystems and the evolutionary forces they are experiencing during their life cycle. In this framework, progeny of hatchery-produced fish that spawned naturally could be considered part of the ESU, provided that their parents were still part of the evolutionary lineage that characterizes the ESU.

Although the ecological-context approach to define ESUs was developed to address a practical problem in applied conservation biology involving captive breeding, the principles underlying the approach could be applied beyond hatchery-wild issues. For example, a situation somewhat analogous to the captive-wild issue arises within the species *Oncorhynchus mykiss* in considering the ESU relationships between resident (rainbow trout) and anadromous (steelhead) life history forms. Three generic types of relationship between the two forms can be identified (Good *et al.*, 2005): no physical barriers to interbreeding between the two forms, either historically or presently (Case 1); resident fish isolated above a long-standing natural barrier (e.g., a waterfall) (Case 2); resident fish isolated above a recent, man-made barrier (e.g., a dam) (Case 3). Under the lineage-based ESU concept, Case 1 resident fish are considered to be part of the anadromous ESU, Case 2 resident fish are generally considered not to be part of the ESU, and Case 3 situations are evaluated individually (in a way that is analogous to evaluation of individual hatchery populations) to assess the degree of divergence between the life history forms. As outlined by Hey *et al.* (2005), application of the ecological context approach would lead to the same conclusions as above for Cases 1 and 2, but Case 3 resident fish would be excluded from ESUs because human intervention had disrupted natural evolutionary processes and placed the resident fish in a novel ecological context.

Each of these two frameworks has certain advantages and disadvantages. The lineage-based approach is consistent with most published thinking regarding ESU delineations, and it also provides a framework for legal protection of endangered gene pools that exist primarily or entirely in captivity. A disadvantage is that the decision as to how divergent hatchery populations must be before they no longer are part of the ESU is necessarily somewhat arbitrary, and once a standard is established it can be difficult to determine whether the divergence of any particular population meets or exceeds this threshold. A significant advantage of the ecological context approach is its simplicity: To determine the ESU status of an individual, it is only necessary to know whether it was born in a hatchery or has spent a significant amount of time in captivity. Results of applying this framework are also quite predictable, which can be a boon to conservation management and planning. A potential disadvantage is that application of this framework would commonly result in placing parents and offspring in different ESUs – a curious result for a concept based on evolutionary principles.

In 2005, NMFS revised its hatchery listing policy to be consistent with the Alsea decision (NMFS, 2005a) and updated the ESA listing status of Pacific salmon DPSs, based on the new policy (NMFS, 2005b). In one case, although assessments concluded that the wild populations qualified as endangered, the DPS as a whole was listed as threatened because of relatively abundant hatchery fish that were considered part of the DPS. This determination thus followed the stipulation of *Alsea Valley Alliance v. Evans* that hatchery fish must be considered in ESA listing determinations, but assigned a higher priority to the status of wild populations.

In revising the ESA steelhead listings, NMFS had to deal with the relationship of resident and anadromous *O. mykiss*. In previous listing determinations, NMFS had concluded that

all Case 1 resident fish (and some Case 3 fish) were part of the steelhead ESUs; however, the US Fish and Wildlife Service (USFWS), which has ESA jurisdiction over terrestrial and freshwater species, refused to list the resident fish. As a consequence, the previously listed steelhead ESUs had the same legal vulnerability that *Alsea Valley Alliance v. Evans* identified for hatchery fish: resident fish were in the ESUs (and hence part of ESA-recognized DPSs) but were not listed. In finalizing the steelhead listing determinations, NMFS adopted an extreme version of the ecological-context approach, concluding that in general resident rainbow trout and steelhead are in different DPSs, even when they interbreed (NMFS, 2006). A key factor in this approach was the decision to consider steelhead under the joint USFWS–NMFS policy for defining DPSs of vertebrate species (USFWS and NMFS, 1996), rather than under the Pacific salmon ESU policy. The joint policy has a similar two-part test for identifying DPSs but does not use the term “ESU” and potentially provides more flexibility in making DPS determinations. Furthermore, as the USFWS and NMFS share ESA jurisdiction for *O. mykiss*, a logical argument can be made for using the joint (1996) policy for this species.

Subsequent court decisions have supported these listing determinations involving hatchery fish and resident fish. In *Trout Unlimited v. Lohn* (2009), the court held that it was reasonable to focus primarily (but not entirely) on the status of wild populations in determining whether a DPS is threatened or endangered. In *Modesto Irrigation District vs. Gutierrez* (2010), the court found that the ecological-context approach for placing steelhead and rainbow trout in separate DPSs was a reasonable interpretation of existing statutes and the joint vertebrate DPS policy.

Conclusions

Collectively, these two frameworks provide complementary ways of thinking about captive populations and ESUs. In most pristine natural systems, the two frameworks would be congruent. Ecological context to a large extent shapes the evolutionary processes that occur, and evolutionary lineages are the product of these processes. As a consequence, in most natural systems considerations of evolutionary lineages and ecological context would lead to the same conclusions about conservation units. In artificial systems, however, a disconnection often occurs between ecological context and evolutionary lineage. Individuals from the same evolutionary lineage can be abruptly placed in very different ecological contexts, resulting in major differences in the evolutionary processes they experience. Which of the two frameworks is more appropriate for any particular application involving captive populations? There is no single scientific answer to this question. Instead, the appropriate framework should be selected after careful consideration of the advantages and disadvantages of each approach, in light of the goals one is trying to accomplish.

It is also possible to envision the ecological-context approach being applied more broadly defining conservation units in natural systems that have experienced anthropogenic change. Before this happens, however, it would be necessary to consider in more detail how extreme the change in ecological

context must be before the affected individuals can no longer be considered to be part of the ESU. In Pacific salmon hatcheries, direct human intervention plays such a large role in the life cycle that the distinction between hatchery and wild fish is quite clear, at least conceptually. Similarly, a dam that completely blocks migration also severs direct ecological or evolutionary interactions and creates two discrete groups of individuals. But what about a hatchery program that returns fertilized eggs to the wild to hatch on their own? Are the progeny that emerge part of the ESU, since almost their entire life cycle will be spent in the wild? What about dams that are leaky to migration and gene flow in both directions? More generally, what about anthropogenic activities that modify natural environments and hence change the ecological context of individuals and the evolutionary processes they experience? Many of these anthropogenic changes mimic natural processes. For example, habitat fragmentation, which disrupts evolutionary processes within and among populations, is a common result of anthropogenic activity but also occurs in natural systems. Should populations that suffer fragmentation due to anthropogenic causes be excluded from ESUs based on more pristine systems? Human activities have also led to the spread of many species outside their native ranges; many of these flourish in the novel environments, and this changes the ecological context and evolutionary processes experienced by native species. Under the ecological-context framework for defining ESU membership, how would such populations be considered? It is likely that scientists and policy makers will wrestle with these and other questions in the future as they continue the dialogue about how best to conserve biodiversity in human-dominated landscapes.

Glossary

Allee effect Biological phenomenon whereby the survival of the individuals of a population increases by spatial aggregation.

Beta diversity Spatial variation of species diversity across sites within a region community. All forms of life that coexist and interact with each other in a particular habitat.

Community All forms of life that coexist and interact with each other in a particular habitat.

Ecological footprint Cumulative impact of all people.

Ecosystem Complex dynamic system that arises by the integration of a biological community with the physical environment.

Ecosystem services Benefits obtained by people from (fully functioning) ecosystems.

Edge effects Penetration of abiotic and biotic conditions including wind, microclimate, and ecological traps from the matrix into forest interiors that effectively reduces the size of a patch.

Extinction vortex Positive feedback loops that increase the risk of extinction of a population as it declines in size.

Gene bank Facility where genetic material is stored in the form of seeds, pollen, embryos, or semen, or, in some cases, as live plants or animals living in a field, a greenhouse or other installation.

Habitat corridors or connections Strips of habitat that connect isolated habitat patches in a landscape transformed by human land use. Connections can be achieved through the conservation of existing habitat or by ecological restoration.

Habitat restoration Active modification of the current state of a degraded habitat in order to return it to a former, preferred state.

Matrix A heterogeneous area composed of a dynamic mosaic of interacting habitats, some natural and some anthropogenic.

Maximum sustainable yield Policy of maximizing the harvest of natural resources without reducing their future potential which often overestimates yield.

Population A group of individuals with common ancestry that are much more likely to mate with one another than with individuals from another such group.

Systems theory Framework for understanding the dynamics of interconnected components trophic cascade changes in a community as a result of changes in the abundance of a species or group of species.

Trophic cascade Changes in a community as a result of changes in the abundance of a species or group of species.

Definition

The current global crisis in the loss of biodiversity is the result of the immense success of one species, *Homo sapiens*, at the expense of the majority of most other species. Concern about the loss of biodiversity arises from spiritual, moral, and esthetic motives, through economic rationales, to purely self-ish reasons. Moreover, the growth of these concerns has fueled the rapid expansion and awareness of conservation biology into academia, government, industry, and other sectors of society worldwide, earning it the label “discipline with a deadline” (Wilson, 2002). The wider field of conservation relies on efforts across scales, from the vital grassroots at which small-scale solutions to local conservation problems are piloted and where local people act as stewards of natural biodiversity; through the large international conservation NGOs, capable of land purchases, of acting as watchdogs, and of establishing enduring partnerships with governments and private land-owners to governmental agencies that pass and enforce conservation directives. The “formulae” that underpin these efforts come from the science – Conservation

Biology – which aims to translate into practice and action outcomes of prioritization and horizon scanning exercises, and optimize research and monitoring to ultimately influence conservation policy and ensure that it is evidence-based. Although the first conservation biology textbooks and scientific journals date back to the early 1960s, conservation biology’s growth as a scientific discipline during the last three decades has been rapid and global, and is evident in the academic training programs in conservation biology that now span the world.

Conservation biologists have an enormous agenda. Initially, they sought to understand the impact on biodiversity of the complex interactions between human societies and the natural world. They hope this understanding will provide guidelines for minimizing the negative effects of human actions on the persistence of biodiversity. Increasingly, the discipline has grown to recognize the great extent to which humans depend on biodiversity, and has begun to explore the services that natural ecosystems provide to humans. Ultimately, conservation biology aims to guarantee the persistence of natural landscapes, healthy ecosystems, species,

populations, and genes as well as the complex interactions among them and the dynamic processes that characterize them. This pursuit is necessarily trans-disciplinary, integrating the principles and practices of a variety of disciplines, principally ecology, population genetics, economics, and biogeography, but also increasingly anthropology, psychology, education, engineering, law, and public policy.

Ecosystems and Communities

The mandate of conservation biology covers a spectrum that runs from concern about the conservation of large, intact, functioning ecosystems, through the maintenance of viable indigenous human and ecological communities, to the preservation of the last surviving individuals of species in zoos and botanical gardens. Arguably, this spectrum may be extended to include the DNA of currently extant or recently extinct species in museums. This spectrum includes both processes that are complex and only partially understood and ones that are more completely characterized.

The most economical and effective way to conserve biodiversity is through *in situ* protection that guarantees the persistence of all the processes that characterize biodiversity in a fully functioning ecosystem. Biogeochemical and hydrologic cycles, the flow of energy through food webs, and evolution by natural selection all require a complex web of interacting biological and physical elements. It is in general unrealistic to assume that these organisms and the processes they mediate can be removed from the natural setting and recreated in a zoo, botanical garden, theme park, or gene bank. For long-term persistence, they must be conserved where they naturally occur. The most popular instruments for *in situ* conservation are nature reserves and protected areas. According to the International Union for Conservation of Nature (IUCN), a protected area is a section of land or sea especially dedicated to the protection and maintenance of biodiversity and of natural and associated cultural resources, which is managed through legal or other effective means. Protected areas come in many kinds and differ mainly in size and the degree of human intervention that is allowed to occur within them. At one extreme are large, strict nature reserves and wilderness areas, where little or no obvious modification of the landscape is permitted. Examples of these include the Bob Marshall wilderness in Montana, US, and the Parima-Tapirapecó national park in southern Venezuela. At the other extreme are "managed resource" protected areas, which are devoted to the sustainable use of natural ecosystems, such as the networks of game reserves in Botswana or Spain, or community-run "Wildlife Management Areas" (WMAs) in Tanzania. In all cases, the maintenance of ecological and evolutionary processes is recognized as a key motivation for the creation of such reserves, even in the case of WMAs where the proximate goal is to ensure that local people benefit from conservation. Transboundary parks are meanwhile becoming more prevalent, which may be an evidence of improved high-level political cooperation in conservation and natural resource management, and the recognition that animal home ranges often intersect political boundaries.

Ecosystem studies play an increasingly major role in understanding complex ecological systems, and they provide important guidelines for the management of protected areas.

Although there are very few examples of nature reserve systems that were based from their inception on ecological principles, conservation biologists have undertaken many *post hoc* analyses of reserve systems that were originally designated for political, esthetic, and occasionally scientific reasons. For example, Yellowstone National Park in the US, formerly the world's first national park, was founded for the benefit of the people so that they could appreciate its spectacular and unique geohydrothermic features. By chance, it also happens to contain a nearly complete set of the fauna and flora found in the North American Northern Rockies, and thus is also valuable from the perspective of the conservation biologist.

The first systematic approaches to examining the design of nature reserve systems originated in the application of R. H. MacArthur and E. O. Wilson's "theory of island biogeography" to fragmented landscapes. This theory postulates that the number of species on islands is the result of a dynamic equilibrium between the processes of extinction and immigration, such that as island size increases, extinction rate decreases, and as distance from the mainland increases, immigration rate decreases. As a result, a small island located far away from the mainland will achieve a smaller equilibrium number of species than a large island located near the mainland (Figure 1). This led Jared Diamond to suggest a series of geometric arrangements that compared preferred to less optimal distributions of patches of protected habitat (Figure 2).

The creation of a nature reserve may reduce or completely halt habitat conversion within its borders, but is not likely to prevent land use changes in surrounding areas. As time passes, nature reserves become habitat "islands," and may effectively

Figure 1 Theory of island biogeography predicts that the number of species in equilibrium for a small island located far away from the mainland is smaller than for a large island located near the mainland. Redrawn with permission from Wilcox BA (1980) *Insular ecology and conservation*. In: Soulé ME and Wilcox BA (eds.) *Conservation Biology: An Evolutionary-Ecological Perspective*, pp. 95–118. Sunderland, Massachusetts: Sinauer Associates.

Figure 2 According to the theory of island biogeography, large, round, connected, or closely located protected area networks are better for assuring the persistence of a larger proportion of the species present in an area. Reprinted from Diamond JM (1975) The island dilemma: Lessons of modern biogeographic studies for the design of natural reserves. *Biological Conservation* 7: 129–146.

decrease in size while increasing in degree of isolation from the matrix of habitat that once included them. The theory of island biogeography predicts that the equilibrium number of species in habitat islands should decrease until either the effective size of the nature reserve stops decreasing or the effective distance from sources of immigrants stops increasing. Thus the effectiveness of many parks in the long-term conservation of biodiversity is compromised by phenomena such as edge effects, which effectively reduce the size of a patch. At the same time, conventional habitat fragmentation studies have recently recognized the importance of studying fragments within the larger landscape mosaic, paying attention to the vegetation types found between forest patches in the “matrix,” or modified habitats surrounding the fragments. The influence of this matrix on animal and plant dispersal, diversity, abundance, and persistence can have a significant effect on the magnitude of edge effects and will simultaneously modify the effective dispersal rate of different species between patches (Ricketts, 2001).

The SLOSS Debate

With time, conservation biologists have become aware that the theory of island biogeography might offer additional insights to questions related to the design of nature reserve networks.

For example, what sort of actions would the theory prescribe to minimize the rates of species loss? Alternatively, how can a reserve network maximize the number of species preserved? Is there an optimal shape for nature reserves, or can they be arranged in optimal geographic designs?

In attempting to answer some of these questions, conservation biologists initiated a controversy that came to be known as the single large or several small or SLOSS debate. The main point of contention was whether the conservation of biodiversity in a particular area was better served by one large reserve or by several small ones. Proponents of the “single large” approach argued that large reserves were able to house large population sizes, thus minimizing the risk of extinction of the species present. In small reserves, high extinction rates would result in changes of the species assemblages in the reserve and lead to habitats that were very different from those initially targeted for conservation. Proponents of the “several small” approach demonstrated that several small reserves whose combined size equaled that of one single large reserve could include a larger proportion of the species present in a given region. Furthermore, several small reserves generate a set of independent duplicate subpopulations, which decreases the likelihood of extinction of the population as a whole from diseases or catastrophes.

Spatial considerations also play a major role in the size of areas set aside for endangered species. Indeed, the problem of incomplete consideration of spatial scale was at the heart of much of the SLOSS debate. For example, consider a small town that decides to set aside an area of habitat as a nature reserve. At this spatial scale, there is little difference in the species composition of similar-sized patches; however, a relatively small increase in the size of the patch is likely to capture a significantly larger proportion of the local biodiversity. In contrast, as we increase the scale of parks to the state, national, or even semicontinental scale, similar small increases in the area preserved will not significantly affect the species composition in the patch but similarity between patches of habitat of similar sizes will decline. At this national or continental scale, it will be better to purchase, set aside, or otherwise preserve a variety of different patches of habitat. The importance of “beta diversity,” a measure of biodiversity, which represents this variety and can be defined as the change in species composition from place to place, has been increasingly recognized in parallel with the appreciation of spatial scales. Thus, the answer to the SLOSS debate was seen to depend on spatial scale.

Spatial and temporal considerations of scale are also central to our understanding of how ecosystems respond to natural and anthropogenic disturbances. The relationship between the spatial scale of a disturbance, the frequency of a disturbance, and the length of time it takes to recover from a disturbance (the “disturbance regime”) will determine how readily degraded land can be recovered and used to increase the effective size of a preserved area. In habitats that require disturbances such as fire to maintain all their natural components of biodiversity, such as the New Jersey pine barrens in the eastern US, the Fynbos of South Africa, or the Banksia woodlands in western Australia, successful management will have to mimic the scale and frequency of natural disturbances. Some preliminary synthesis suggests that the recovery time

from disturbance, scales roughly with the square root of the area disturbed.

Gap Analysis

Modern reserve design methods seek to maximize the representation of the components of biodiversity in protected area networks while minimizing the resources needed to do so. For this approach to be effective, comprehensive information is needed on the geographical distribution of species from a wide range of different taxa.

The first step in a reserve design process is to select a series of surrogate measures of biodiversity and assess the existing network of nature reserves for how well it samples this biodiversity. This allows managers and researchers to identify components of biodiversity that are unprotected or not well represented in the current reserve network. The spatial configuration of these missing components defines priorities for future protected area designation. This technique, known as *gap analysis*, was pioneered by Australian scientists in the mid-1970s and popularized by the US governmental agencies in the decades that followed, particularly Michael Scott and colleagues in Hawaii and Idaho.

Gap analyses typically focus on well-known species or groups of species, and assume that their presence in a nature reserve network can be used as an indicator of the presence of other components of biodiversity as well. Gap analyses may be carried out on the basis of climatic zones, landscape properties, or any subset of features in a geographical region and for any proportion of population size or geographical extent. In fact, given that for most regions of the world knowledge of the detailed distribution and abundance of species is quite limited (although camera traps have recently improved our ability to pick up rare and elusive species), the best available data may be a combination of abiotic environmental parameters that are known to correlate with the biological species of interest. These data can then be integrated into a program of biological surveys that constantly adds new information to the database.

Figure 3 depicts the steps in a gap analysis. This process frequently employs “remotely sensed” data obtained from satellites and requires the use of geographical information systems (GIS). Maps of the distribution and abundance of plants and animals, vegetation types, topography, climate, and soil properties (among other possible data sources) are combined to generate overlay maps that quantify landscape heterogeneity. A map that combines existing protected areas is contrasted with the target features overlay map and the presence of these attributes in the nature reserve system is assessed. Thus, a final map with the distribution of those attributes that are not included in nature reserves allows for the identification of gaps in protection.

The definition of what constitutes adequate representation is the next challenge. Assessors may be interested in ensuring that all species, communities, or habitats considered important are present at least once in a network of protected areas. After achieving this most basic objective, other criteria may be added that minimize costs or future threats, or that maximize the total area of the reserve system by considering alternative configurations of land. It may also be possible to select

Figure 3 Schematic of the gap analysis process.

alternative configurations to reduce conflicts with alternative land uses for the area under consideration.

An important problem that arises is that even if a species is present in a protected area at the time of designation, this does not ensure that this species will persist in the long term. Furthermore, the presence of a set of target species does not ensure that their parasites, predators, prey, or mutualists are also included, or that other unrelated species will be present as well. The protection of a target species may not provide an adequate measure of the status of ecosystem services, such as the prevention of erosion or the pollination of crops. However, these are not necessarily weaknesses of the gap analysis process itself, but of the way in which it is implemented. The use of proxy species (indicator, umbrella, keystone, flagship; see Tim Caro’s *Conservation by Proxy*) must thus be done with care, taking species interactions and food webs into account. Their use may be most appropriate under conditions of uncertainty when the number of species being protected is uncertain and the spatial scale is of intermediate size (Caro, 2010; see **Figure 4**).

Reserve Selection Algorithms

The costs of administering a reserve network increase proportionally to the area protected. Two fundamental concerns of protected area designers are to efficiently allocate available resources, and to minimize the area required to protect as many natural features as possible. The efficiency of a reserve network can be described by the efficiency (E) index

$$E = 1 - (x/t)$$

Figure 4 Use of surrogate species or species groups for conservation planning rests on the assumption that surrogates represent an entire pool of species or subsets of this pool. Reprinted from Wiens JA, Howard GD, Holthausen RS, *et al.* (2008) Using surrogate species and groups for conservation planning and management. *Bioscience* 58: 241–252, with permission from University of California press.

where x is the number or area of the sites required to achieve a particular representation target and t is the total number or area of sites to choose from. Thus, a network of protected areas is more efficient as the amount of land required to achieve the target decreases.

Reserve selection algorithms provide systematic means for designing efficient reserve networks. They follow a step-wise process for choosing a subset of sites from a list of proposed sites, such that the efficiency of the chosen subset is maximized. In other words, these algorithms allow for the selection of the minimum amount of land that is required to include all target species (or other attributes) at least once. There are three types of reserve selection algorithms. “Richness-based” algorithms begin the process by selecting the site containing the greatest number of species or attributes and sequentially adding those sites that include the greatest number of new species, until all species have been accounted for. “Rarity-based” algorithms select sites on the basis of rarity scores, favoring sites that are richest in species with restricted ranges. The third type of algorithm depends on linear-programming techniques, which sequentially search the database of available sites for replacement sites that increase the efficiency of the current set.

Although richness-based algorithms are the least efficient, they are the easiest to implement and have the advantage of including the principle of complementarity, i.e., at each step of the process, the selected site is most complementary in terms of the features that it adds to the set. Rarity-based algorithms tend to be more efficient than richness-based algorithms; by focusing on species with restricted ranges, more wide-ranging species tend to be included by default, and fewer sites are required to achieve fairly complete levels of coverage. Though linear-programming methods are ultimately the most efficient, they rely heavily on intensive computing and are prohibitive for very large data sets.

Reserve selection algorithms allow for the selection of efficient reserve networks, but focus only on the adequate representation of a set of species or habitats within the landscape. They do not provide answers to questions related to the size, shape, or number of protected areas that are required to ensure viable populations of different species, nor do they guarantee ecosystem functions and services. These more ambitious targets may only be achieved by expanding reserve

networks as an interconnected system that allows the interaction of biological and physical components in a continuous landscape.

Corridors and Connectivity across Landscapes

Although overexploitation is responsible for the extinction of some species, the majority of species have declined because of the loss and fragmentation of their natural habitats, combined with the introduction of alien competitor, predator, pest, and pathogen species. It is these indirect effects of human development that have had the biggest impact on biodiversity. The crucial, and perhaps the only, way to minimize future impact is to reduce current and future rates of habitat loss and to explore ways of expanding current systems of reserves through the protection, restoration, or development of large-scale connections across the landscape.

Isolation of nature reserves and protected areas can often disrupt or break migration corridors that are used by seasonal residents of the park, and often increase human-wildlife conflict outside of reserve boundaries. The regular movements will range from the diurnal movement of snakes, birds, and many other organisms between feeding and nesting or brooding sites, to the larger annual migrations of large ungulates such as wildebeest and megaherbivores such as elephants. In some instances, it is possible to maintain needed connectivity between habitat fragments by protecting natural corridors or stepping stones of appropriate habitat. In other cases, natural habitat and stopover points may be lost and enhancement of these converted habitats through ecological restoration may be the only option. The interactions between protected areas and developing or developed areas of human use outside them are often subtle and complex. Increased isolation is likely to lead to changes in the flow of nutrients and pollutants into and out of the protected area. Habitat conversion in the surrounding matrix facilitates the invasion of alien species that interfere with the species that the reserve was designed to protect.

Corridors and connections in the landscape have two major functions at the species level. First, they permit regular daily or seasonal movements, helping to ensure that different sub-sections of larger populations may have access to all the resources they require, while also maintaining the potential for all individuals in the population to successfully interbreed. Second, connectivity facilitates the dispersal of animals from their place of birth to their adult home range where they breed. At the regional or landscape level, this latter function is usually the most important, justifying, for example, the achievement of connectivity between mountain ranges in the western US for the long-term conservation of fully functioning ecosystems.

The restoration of connectivity must occur at many scales. Most attention to date has been paid to local and regional connectivity as a way to redress the various forces threatening small populations. For example, amphibians must be able to move safely across a country lane during their annual migration to a breeding pond. However, many regional and inter-regional corridors have additional goals, such as accommodating the need for grizzly bears (*Ursus arctos*) to

disperse safely between the Canadian Rockies and the Northern Rockies of the US. In the face of global climate change and other major environmental changes, a substantial system of landscape connections is a major prerequisite for ensuring species persistence. Some species may be more suitable indicators of landscape connectivity than others, for example, wolves managed to initially recolonize Yellowstone National Park by dispersing down the chain of protected lands and National Forests before they were experimentally reintroduced into the park. Once they were formally reintroduced and monitored with radio-collars, they have provided vital information on remaining natural corridors that connect Yellowstone to other parks and protected areas.

Species and Populations

Although conservation at the ecosystem level is the most effective way of conserving biodiversity, a significant proportion of research within the discipline of conservation biology has focused on conservation at the population level. This emphasis on species and populations partly reflects the constraints contained within legal mechanisms to preserve biodiversity; for example, both the Endangered Species Act in the US and the global IUCN Red Lists of Threatened Species focus on conserving species and populations. However, the species also offers a relatively well-defined (although not unambiguous) biological unit of study. For example, trophic cascade effects from the loss of single species can occur particularly if the species lost are strongly interacting ones (e.g., fig trees considered to be keystone, and deer, known to be dominant). Conserving distinct populations of a species is also justifiable when behavioral diversity is taken into account (i.e., the loss of one population means the loss of an entire set of adaptive behaviors). Variety buffers the species “from the ups and downs” of life. Although it is understood that species diversity keeps ecosystems healthy, this approach emphasized that population diversity is also key. Research on several hundreds of discrete populations of salmon in Alaska illustrates how each population can do better or worse according to certain environmental and random conditions. At any one time, a high diversity will provide enough populations experiencing a productive time, thus compensating for those populations doing less well.

Finally, thinking about a population of populations or a metapopulation, has direct relevance to reserve planning when incorporating linkages that connect isolated fragments into the design.

The global biodiversity crisis is often most effectively communicated in terms of increasing extinction rates or numbers of threatened species. Therefore, awareness building and fund-raising tend to be more successful when focused on a species, rather than an ecosystem or a particular environmental problem. It is often easier to raise funds or public support for charismatic species, such as elephants (*Loxodonta* sp.), chimpanzees (*Pan troglodytes*), or giant pandas (*Ailuropoda melanoleuca*), than for a generic habitat, such as a tropical or bamboo forest. More pragmatically, it is often possible to use the requirements of a single species to maintain the viable complexities of entire biological communities or

ecosystems. By focusing on either a target species that occupies a keystone position in an ecosystem or a species that requires large tracts of land to persist (often referred to as an “umbrella” species), many other additional species and their natural habitats are also protected. This is effectively the strength of the “jeopardy amendment” in the US Endangered Species Act, which provides legislation that is designed to conserve habitat in order to ensure the viability of one specific species – as occurred with the northern spotted owl (*Strix occidentalis caurina*) and “old-growth forest” in the north-western US. Similar species-centered approaches led to the creation of the Cosk-somb Basin jaguar (*Panthera onca*) preserve in Belize, the Arabian oryx (*Oryx leucoryx*) sanctuary in Oman, the Laguna Brava vicuña (*Vicugna vicugna*) reserve in Argentina, the Wolong and Wanglang nature reserves for panda habitat protection in China, and the significant expansion of the El Guácharo national park in Venezuela to secure feeding habitat for a large oilbird (*Steatornis caripensis*) colony.

Population Viability Analysis

The central theme of population ecology is represented in a large canon of work that examines how populations respond to intrinsic and extrinsic factors and how these affect their long-term dynamics and persistence. Although deterministic, stochastic, environmental, demographic, and genetic processes can all have complex and interacting effects on extinction risk, these processes tend to operate in a hierarchical fashion determined by the size of the remnant population. Furthermore, habitat destruction and overexploitation can exacerbate intrinsic risk factors and accelerate population declines. A population viability analysis (PVA) explores the interactions between different known factors and assesses the likelihood that a population will become extinct within a specified time frame and under particular circumstances. PVAs generally require the use of computer simulations and simple mathematical models. The work of M. A. Burgman, S. Ferson, and H. R. Akçakaya (1993) provides the definitive introduction to this area.

Population viability analyses are a valuable tool for conservation biologists concerned with studying the long-term persistence of particular species or populations. In the early 1980s, Mark Shaffer introduced the concept of the minimum viable population (MVP), as the minimum size required for an isolated population to have a 99% chance of remaining extant for the following 1000 years in a particular habitat. Shaffer's work provided a quantitative framework for thinking about species conservation objectives and the timescales within which human actions should be considered. While focusing on the MVP concept, researchers began to realize that the key to conservation at the population level was understanding the impact of different stochastic and deterministic processes that determine extinction risk. By examining the sensitivity of the population to changes in these processes, it was argued that management actions could be taken to increase population persistence. Although there was an unfortunate tendency for many early analyses of viability to emphasize captive breeding as a means of enhancing persistence, this is now perceived as an option of last resort. Moreover, the notion of an MVP was progressively assimilated into

a series of techniques that are known as “population viability analysis.”

PVAs focus on individual species, but they can also examine the potential consequences of different ecological factors, including interactions with other species, rates of habitat conversion, or management interventions that may be taken to improve population persistence. When integrated sensibly into wildlife or endangered species monitoring programs, PVA can be a powerful tool to assist in decision making within an adaptive management framework, but to be complete it requires years of data. The degree of complexity of a PVA will depend on the number of elements that a manager decides to consider, yet more complex models do not necessarily mean more useful results. Understanding the model structure and its sensitivity to varying parameter values may be more important than the modeling process itself. Numerous PVA software packages are available. Unfortunately, the different assumptions hidden within different packages mean that they can produce very different results from the same set of data. Thus, it is crucial to bear in mind that PVAs should not be used to estimate extinction risks *per se*. Instead, they are most useful for ranking different management options to determine those that increase the likelihood of persistence and that can be implemented at lower costs. They are also invaluable for indicating areas of ignorance about a species and thus focusing future research. The precautionary principle indicates that ignorance should always imply increased protection until a more complete set of demographic data on the species is available.

The Demography of Small and Declining Populations

The recognition that current losses of biodiversity constitute a global crisis has led to a growing interest in the problems faced by small populations. By definition, all populations that go extinct first become small. Research in this area has emphasized the positive feedback between a number of mechanisms, each capable of increasing extinction risk as populations further decrease in size. The four principal mechanisms are (1) chance demographic events (demographic stochasticity), (2) environmental stochasticity, (3) inbreeding depression, and (4) allee effects due principally to the breakdown of the social benefits accrued by living in groups. Unfortunately, in the 1980s this “cult of the extinction vortex” led to an emphasis on crisis management, whereas relatively less attention was focused on understanding the processes that initially caused the decline in a previously viable population. In an insightful review of population-level approaches to conservation biology, Graeme Caughley (1994) proposed that the discipline has developed along two relatively independent but complementary lines: the “small population paradigm,” which has received more emphasis and addresses problems related to the persistence of small populations, and the “declining population paradigm,” which considers the causes of population declines and how to reverse them.

In broad terms, “small population” conservation biologists have focused on finding ways of increasing the size of small populations and achieving the maintenance of a regular flow of individuals between fragmented populations. The

application of these principles to the conservation of endangered species in the wild has been limited, but they have played a major role in influencing captive breeding practices, while providing some insights into the theory of how nature reserve systems might be designed.

In contrast, an increasing number of conservation biologists have focused their research on identifying the causes that lead to declines in species abundance or the contraction of the range of a species. The primary forces operating here are habitat loss and fragmentation, although threats posed by alien species, over-exploitation, and pollution are also important, as are species traits that may predispose them to extinction such as rarity, island endemism, and ecological specialization. By examining populations at an earlier stage in their decline, it is hoped that strategies may be found for halting and reversing the decline. This paradigm is concerned with prescribing early, preventative actions that require minimal intervention that may be taken before a population becomes seriously endangered. At present, this approach has not succeeded in generating elegant theoretical principles to guide management decisions. This is mainly because population declines can be caused by numerous factors operating simultaneously on a community of populations. Not surprisingly, these effects are difficult to quantify. The key to future success in this area is carefully designed experimental and monitoring programs that systematically seek causes for population declines.

The most likely future for these two paradigms is eventual fusion. Clearly, both approaches are useful and contribute complementary insights to the advancement of the discipline.

Individuals and Genes

All forms of life carry genetic information. In the long term, the capacity of any species to adapt to anthropogenic and nonanthropogenic changes in the environment will be related to the existence of genetic variation. *In situ* conservation programs are almost without exception the best option for conserving the genetic diversity that is a component of biodiversity. The protection of an ecosystem and its ecological processes provides the necessary conditions for evolution and natural selection to proceed. Additionally, protecting species in the wild is much more cost-effective than maintaining them in captivity. In the cases of some species, however, such as varieties of domesticated plants and animals and highly endangered species, *ex situ* conservation technologies are required. In these cases, the maintenance of genetic variation becomes a central topic of concern, especially if an endangered species is taken into captivity for future reintroduction into the wild.

Measuring Genetic Variability

Genetic information is encoded in genes, which are mainly composed of long chains of deoxyribonucleic acid, or DNA. Genes aggregate in the cells of every organism to form chromosomes. Variation in genetic information can be measured at any step of the biological process that transforms

the sequence encoded in genes into its protein products. This information can then be used to quantify differences between organisms, populations, species, or any other taxa.

Methods for measuring genetic diversity focus on the variation of “markers,” much in the way that gap analysis uses species or topographic variables to characterize the degree of spatial heterogeneity in a landscape. These markers are assumed to correlate in a broad sense with the genome as a whole; the more variable a population is at marker loci, the more variable it is overall. In the past, scientists were limited to examining indirect or “phenotypic” measures of genetic diversity through markers such as variable external morphology or coloration, intracellular concentration of secondary compounds such as phenolics, cell pigments, or hydrocarbons, and variable protein products called “allozymes,” which may be visualized using electrophoresis. In recent years, however, biologists have developed techniques for examining the DNA itself. This permits the use of markers such as the presence or frequency of specific base-pair sequences in DNA molecules. DNA fingerprinting, for example, allows the characterization of differences between individuals in a population on the basis of patterns in the variation of minisatellites, or relatively short (10–50 base-pairs long) repeat sequences that are distributed in tandem arrays throughout the nuclear genome. Variation in organelle DNA (such as mitochondria or chloroplasts) may also be examined. Different versions of these techniques are used to assay genetic differences within and between populations, species, or other taxonomic levels.

DNA fingerprinting is being increasingly used in the field of wildlife forensics to trace, for example, the source of elephant ivory seized on the black market.

The Role of Zoos, Aquaria, Botanical Gardens, and Gene Banks

In extreme cases, such as when the last few remaining individuals of a species are under imminent threat in the wild, or when a wild variety of a particular crop is being rapidly replaced by modern monocultures, the maintenance of populations in captivity may be the only short-term action to prevent their extinction. Zoos have played an important role in preventing the extinction of the Arabian oryx, the peregrine falcon (*Falco peregrinus*), and the Guam rail (*Rallus owstoni*), but in all cases the captive facilities were used to buy time while the agents of decline were being dealt with. Gene banks may be the last resource for hundreds of threatened varieties of domestic animals and plants. The Royal Botanical Gardens in Kew (UK) hold about 38,000 species in their collection; Brazil and Colombia are the only countries in the world that have more species within their territories.

The primary functions of these captive facilities are not to save endangered species, however, to promote education and research; for example, many captive facilities now maintain web-based repositories of data (e.g., eTaxonomy projects) updateable in real time. Kew Gardens’ e-monocot site, for which Kew employed the emerging science of Biodiversity Informatics, is a database of the world’s monocot plants and facilitates their identification and classification. While conservation objectives are clearly most effectively and efficiently

achieved by *in situ* rather than by *ex situ* approaches, zoos, aquaria, and botanical gardens provide visitors with an opportunity for close interaction with a wide variety of plants and animals that are otherwise out of reach for most people. Zoos attract millions of people worldwide and are good facilities for educating them about the challenges and opportunities created by the present biodiversity crisis. They are also potentially important facilities for raising funds that can then be invested in conserving habitat in the regions where the animals and plants on display originally came from.

Future Challenges

The future of conservation biology lies in teamwork, bold vision, and allocation of more time to action and less to assessment. The complexity of issues surrounding the conservation of biodiversity requires a trans-disciplinary approach that integrates knowledge and expertise from both the natural and social sciences. Conservation biology will also become increasingly cross-institutional as governments, academia, and nongovernmental organizations work together on the same issues but with complementary approaches and points of view.

Of the 47,677 species assessed in 2009 by the IUCN, nearly 40% were found to be threatened with extinction. Meanwhile, conservation biology is becoming less species-oriented, more holistic, and systems-oriented. The expansion of protection from species to ecosystem springs in part from a transition to thinking about systems as dynamic. A new Red List aimed at ecosystems rather than species was recently conceived (Rodríguez *et al.*, 2011; Figure 5).

In recognizing the dynamic nature of ecosystems, the discipline is moving away from arbitrary numbers – both minimum and maximum. For example, with regards to MVP, there is now consensus that no single rule of thumb exists for a safe minimum size of populations that differ in the levels of environmental stochasticity that they confront. Whereas, capping populations of large mammals (elephants, wild horses) at specific numbers on the basis of human-defined carrying capacities (based on, e.g., viewing conversion by elephants of woodland into bush as disturbance rather than ecosystem engineering) is increasingly seen as an old-fashioned management strategy.

One requirement of conservation biology in the future will be the design of biodiversity management programs and decision-making mechanisms that incorporate, rather than reject, uncertainty. For example, if we were to wait until all the desired data on a country’s corridors were collected and compiled before protecting them, we may lose vital, quickly-disappearing corridor routes. Rapid assessment exercises combined with local knowledge (“citizen science”) may therefore, in some instances, do more for conservation than detailed priority-setting exercises. We must ask “how much evidence is enough for “evidence-based conservation?” and also “how can we balance concern over collecting enough data with ensuring that we do not duplicate efforts?”

Although necessary, the establishment of parks and reserves may become viewed as “desperate action” by which we cannot ensure by law that what happens on one side of the

Figure 5 Ecosystem extinction-risk assessment entails evaluating data on one or more quantitative proxy risk indicators (criteria) against thresholds to assign a threat category (critically endangered (CR), endangered (EN), or vulnerable (VU)) to the ecosystem. Reprinted from Rodríguez JP, Rodríguez-Clark KM, Baillie JEM, *et al.* (2011) Establishing IUCN Red List criteria for threatened ecosystems. *Conservation Biology* 25: 21–29.

line does not happen on the other (Adams, 2006). With growing agricultural expansion, pollution, overharvesting and climate change, many of these protected areas are failing in their stated aims, losing these target species or habitats (Graham *et al.*, 2008; Mora, 2008; Craigie *et al.*, 2010). Coupled with growing pressures from expanding populations and the need for more agricultural land, many protected areas are going to be under pressure for conversion and, with their conservation targets in decline or lost it will be hard to justify their existence. Lastly, the development of roads and more optimistically railways will significantly improve the infrastructure of many Southern Nations, particularly in sub-Saharan Africa and South America; however, these routes will open up huge areas of wilderness for exploitation, while simultaneously allowing access to invasive alien plant and animal species as well pathogens. How can we strengthen laws and economic arguments that recognize that natural ecosystems require protection while at the same time moving away from fortress conservation to multi-use management schemes such as biosphere reserves and transboundary parks? Multiple-use zones such as the ones around Masoala National Park in Madagascar have worked well to buffer the park and support local livelihoods. Concurrently, the biodiversity value of plantations and agro-forests is increasingly acknowledged.

There is better recognition of the need to more accurately map the spatial distribution of the natural ranges of species and to monitor the abundance of as many species as possible. This will allow us to more accurately assess how species will respond to the twin threats of climate change and habitat loss. Simultaneously, the authors are concerned that the interest in climate change has detracted from habitat loss as the major threat to biodiversity. The impact of climate change over the next 25 years is most likely to be strongest in polar and temperate regions, there will be less of an impact in the Tropics

and indeed, the loss of habitat in the tropics due to agricultural expansion may leave very little biodiversity to respond to climate change (Jetz *et al.*, 2007).

New conservation biology books will be aimed not only at intellectual communities but at laymen; notable recent ones include Jonathan S. Adams', *The Future of the Wild: Radical Conservation for a Crowded World*, which urges combining science with traditional knowledge and economic sense and "saving some of everything" in the spirit of thinking big; and *Conservation Biology for All*, available online (<http://www.dbs.nus.edu.sg/staff/sodhi.htm>).

The conservation biologist's toolbox is growing to include emerging technologies such as camera traps and established ones such as cellular phones; and also stable isotopes; genetics and genomics, DNA fingerprinting; modeling; Bayesian inference; geographic information systems and remote sensing (Figure 6).

Four important recent developments that will help buttress the efforts of conservation biologists include the Millenium Ecosystem Assessment, Convention on Migratory Species, the Intergovernmental Platform on Biodiversity and Ecosystem Services (IPBES), and Reducing Emissions from Deforestation and Degradation (REDD). The authors highlight IPBES and REDD here. Established in 2010 (the International Year of Biodiversity), IPBES is aimed at peer reviewing biodiversity research to make certain that governments receive the most up to date information and evidence-based recommendations. IPBES has been dubbed the "IPCC for Nature" as it bears resemblance to the Intergovernmental Panel on Climate Change (IPCC), a global organization that has helped raise awareness and promote action on climate change. The IPCC, although a good model, has not been free of flaws and criticisms, but it has succeeded in identifying issues on which there is consensus (for example, that much of the warming

Mobile Phones: Readily accessible and affordable, mobile phone use has exploded in developing countries and improved voice communications. Applications in field biology range from tracking animals to providing early warning of environmental crises, facilitating rapid responses by rangers, park managers and communities to threats such as poaching, fire, and encroaching wildlife (Banks and Burge, 2004). New devices combining GPS and mobile phone technology are leading to low-cost alternatives for animal tracking equipment. See: <http://www.kiwanja.net/wildlive!.htm>

Camera Traps: Self-contained surveying tool that provides data on the presence and movement of elusive and rare wildlife species. New cameras capture video, which can provide clues about the behavior of such species. Combined with computer software, individuals can be identified enabling the use of capture–recapture analysis to estimate species abundance and density.

Global Positioning System and Geographic Information Systems: GIS is used to process geo-referenced data from a GPS (hand-held units and wildlife collars) and integrate it into a map project to plot species movements, home ranges and habitat use. Combined with modeling techniques such as habitat suitability and CorridorDesigner, researchers can model species distributions and design linkages between habitat patches. Other uses include anti-poaching and land-use planning.

Stable Isotopes Analysis: The abundances of stable isotopes, atoms that do not undergo radioactive decay found in most elements, are used as a recorder to reconstruct ecological processes (e.g., climate from tree rings) and trace ecological activities (elephant migration routes and dietary patterns from stable isotopes found in teeth and hair). <http://isoscapes.org>

Genotyping: New molecular techniques may offer a way to obtain more reliable estimates of population size. Animal faeces are typed for microsatellite loci using genotyping. Mark-recapture models can then be used to analyze faecal genotyping data treating the same multilocus genotype as a recapture.

Mathematical Modeling: A variety of models of harvesting, predator–prey and host–parasite dynamics, and optimization, are widely used in conservation ecology and are becoming more accessible to field biologists (see Kokko, 2007).

Network Analysis: Focuses on patterns of relations within a system. A popular application is network representations of ecological interactions such as food-webs to analyze diversity, stability and response to perturbations; another is spatial networks to represent species' dispersal pathways between fragments. See Cumming *et al.*, 2010.

Web-based Data Repositories: Ranging from species cataloging projects to compilations of images and references, web based databases are increasingly a part of conservation projects aimed at making biological data readily and freely accessible. For a comprehensive annotated list of biodiversity databases, see <http://www.biodiverselife.com/biodiversitydata.html>

Media Training: Prepares biologists for interactions with journalists by helping them to communicate research findings accurately, often in everyday language and in a way that grabs attention.

Figure 6 The conservation biologist's expanding toolbox. <http://www.corridordesign.org/>

observed over the last five decades can be attributed to human activities). Given that 20% of global greenhouse gas emissions is due to deforestation, REDD was established to provide incentives (in the form of forest carbon stocks) for developing countries to reduce emissions. Some scientists (e.g., Sutherland *et al.*, 2010) have expressed concern over REDD's emphasis on forests, which could possibly undervalue the high carbon sequestration potential in non-forested ecosystems such as savannas, mangroves, and peat.

Although our understanding of ecosystem function and human dependence on nature's services has greatly increased, it is still far from perfect. We still do not have the equivalent to the chemists' Michaelis–Menten relationships that allow us to say what proportion of habitat loss will lead to a 50% decline in the rate at which a specific ecosystem service is delivered. Although there are logical reasons to assume that ecosystem services may be lost in a consistent order as species from sequentially lower trophic levels go extinct, there have been very

few attempts to systematically organize studies of ecosystem services along these lines (Dobson *et al.*, 2006). As in the case of global climate change, we might never understand every detail of the numerous processes that influence biodiversity and the delivery of ecosystem services, but the need to understand their relationship within a quantitative analytical framework is increasingly urgent. This ignorance cannot remain an excuse for inaction.

Ultimately, conservation of the world's remaining biodiversity will require the adoption of an adaptive management framework that consistently embraces the precautionary principle in combination with the best science available to decide on issues of land stewardship. One of the most difficult issues may be the revision of current resource consumption patterns, particularly in the developed world, and the design of new paradigms and technologies to attend to the needs of a growing and increasingly hungry global population. This retains its status as the major driver of biodiversity decline and the reason for the conservation biologist's task becoming a juggling act of science and advocacy. After particular actions are taken, their success may be monitored and adjusted in response to changing conditions, which arise because of either abrupt, unanticipated events or slowly evolving processes. With time, our understanding of biodiversity and our management decisions will both improve, generating creative solutions to reduce the impact of humans on Earth's systems while assuring the quality of life of all those who inhabit the planet.

Glossary

Ecological integrity The balanced state of an ecosystem under normal environmental conditions, including the capacity of an ecosystem to absorb disruption and also to recover from it.

Ecosystem engineers Animals (e.g., beavers) that modify an ecosystem by physically changing it (e.g., building dams) or by being present in such a great abundance (e.g., large grazing animals) that they have a disproportionately large impact on the ecosystem functions.

Ecosystem management Approach to management that attempts to maintain high ecosystem integrity while providing the services, uses, values, and products from that system for the long term. It explicitly integrates social, economic, and natural system sustainability.

Invasive species Native and exotic species that are capable of displacing indigenous species or spreading into habitats where they were not common previously.

Keystone species Species whose presence and abundance controls the integrity of a community or ecosystem and allows that system to persist within its natural range of environmental conditions.

Legacy ecosystems Ecosystems that carry an intact “memory” of a change in some physical, chemical, or structural attribute or a change in species composition that modifies the resistance and resilience characteristics of the ecosystem.

Resilience Rate at which an ecosystem is able to recover to conditions similar to those that existed prior to the imposition of a disturbance.

Restoration Reestablishment of similar structures and functions of an ecosystem or parts of an ecosystem that are no longer present because of past land uses or disturbances.

Sustainability State that defines the biogeophysical, economic, social, cultural, and political thresholds in between which, it is acceptable to continue to use and obtain services or products from a given piece of land. This definition requires all five factors to be considered when determining whether future generations will be able to acquire the same natural resources as the current generation.

Sustainable development Meeting human needs without damaging the ecosystems that produces these resources and at the same time providing equitable distribution and access to these resources around the world.

System functions Processes that occur in an ecosystem that are typically measured as changes in the carbon or nutrient cycles regulated by decomposers, consumers, or primary producers.

Umbrella species Species that have either large habitat needs or have other requirements whose conservation results in many other species being conserved at the ecosystem or landscape level.

Introduction: New Concepts in Conservation

The discipline of conservation biology arose from the need to apply science to the protection of species that are threatened or on the brink of extinction. In its early years, biologists and ecologists had to worry about refining the science of protecting endangered species on particular tracts of land. This resulted in a conservation science which was very species focused. Nowadays, conservation biology has to resolve many conflicting social, ecological, and economic demands that are simultaneously being placed on ecosystems services provided by particular tracts of land. Saving endangered species is typically only one component of a larger task to protect the entire biotic community (biodiversity) that make up the whole ecosystem. This ecosystem perspective has placed an emphasis on putting into practice many of the holistically based philosophical ideas that were previously articulated by John Muir, Aldo Leopold, and other visionary thinkers. The mounting worldwide conflicts over the conservation of biodiversity and other uses of the same land base make it

imperative to refine and test new models of conservation that are ecosystem based, socially applicable, and culturally compatible. The following example regarding tropical conservation illustrates the contemporary efforts occurring at the ecosystem level that address the human environment as well.

As documented by the United Nations, fully one-half of the world's biodiversity is found in tropical ecosystems where conflicts over resource uses are particularly intense. At the same time, the human population growth rates in these areas are double the world average placing increased pressures on consuming finite bio-resources and their ecosystem services. Such prodigious growth typically leads to a high level of poverty that brings conflicts over resource use and their protection particularly polarizing for resource managers and policymakers who are unable to satisfy all the stakeholders simultaneously. In these circumstances, even the best scientific knowledge about the ecology of groups of species will not provide the needed insight to protect biodiversity, since human demands on the natural resources will constrain the application of science to conservation. Therefore, the

traditional model of conservation, whereby scientists continually refine and apply knowledge to the cause of species preservation, will be insufficient to meet the challenges of the future.

This knowledge has made us realize that the use of species demographic data is generally inadequate by itself for gauging conservation success and therefore for maintaining a species in the landscape. Species demographic data are effective in conservation when the species are keystone or umbrella species, or when they perform the ecosystem engineering functions. Even then, knowledge of changes in population dynamics of a species does not necessarily provide a mechanistic understanding of the role that species play in the ecosystems. But when species data can be linked more effectively through geographical information systems and comparative global data bases, species data can be combined with other aspects (ecological, hydrological, societal etc.) to display dynamic interactions. Conservation has thus been moving towards holistic analyses of systems (i.e., ecosystem management) in which factors other than species biology dictate the approaches used to maintain species in their habitats. A holistic analysis also recognizes that humans are an integral part of the system and not external to conservation projects.

Managing the impacts of human behavior in conservation landscapes continues to be the most challenging and is being aggravated by increased societal and natural environment vulnerability to climate change. This challenge has stimulated the development of many new approaches and tools in conservation. Five major philosophical changes are commonly mentioned while discussing the need to adapt old models and to find new models for conservation:

- First, there is the recognition that a focus only on species is inadequate to conserve species within habitats in perpetuity.
- Second, there is the realization that the human dimensional aspects of ecosystems cannot be ignored if conservation efforts are to succeed.
- Third, ecosystems are dynamic, so the maintenance of a particular type of habitat in the landscape will require several examples of that habitat existing elsewhere within that landscape but at different successional stages. This approach will require a landscape that is sufficiently large to include these stages. If the appropriate conservation area has been selected, when a particular habitat is lost at one location, its replacement will be developing at the same time in another part of the landscape.
- Fourth, conservation approaches will have to incorporate the tools of restoration ecology to re-establish the structural and functional aspects of native habitats required to maintain species. The restoration of damaged habitats is central to the conservation practice since centuries of human modification of the natural environment have resulted in an inadequate habitat area or have significantly modified ecosystems.
- Fifth, disturbances (e.g., hurricanes, and droughts or floods associated with El Niño) at long time-scales can eliminate or modify the habitat set aside in nature reserves so that the species being conserved are unable to survive in that diminished or altered habitat.

These five changes in philosophy are causing a reassessment of how conservation biologists approach the practice of conservation. These changes are partially being driven by new scientific understandings that have been integrated into conservation during the last 20 years. In this article, we present a case for the need to increase the acceptance of these concepts so that conservation practices can become more effective in human dominated landscapes. These five major philosophical shifts have already changed the practice and implementation of conservation projects (the most common changes are summarized in [Table 1](#)). These shifts will be discussed in greater detail in the next sections because they are critical for increasing conservation efficacy (the reader is encouraged to consult the Reference list for further readings on these topics). The Section, Analysis of Evolving Thinking in Conservation Biology will present an analysis of two critical drivers contributing to our evolving thinking in how to practice conservation. The section, Tools for Managing and Conserving Species will present a brief discussion of the contemporary tools and approaches used in conservation in the context of these philosophical changes. The Sections, Conservation in Human Altered Landscapes and Future Directions and Emerging Challenges in Conservation will provide brief discussions of the continuing difficulty for integrating the social and natural environments in conservation projects and the emerging challenge posed by climate change.

The past difficulties experienced in implementing conservation in human landscapes has clearly shown that sustainable economies must be created at the local level for conservation projects to be successful. This recognition influenced the explicit linking of conservation with international sustainable development projects, especially in the humid tropics. Projects that meld these dual objectives are commonly called Integrated Conservation and Development Projects (ICDPs). These projects vary in scale and scope but typically include one or more of the following topics as a central theme: biosphere reserves, eco-tourism ventures, nontimber forest product harvesting, and regional land use plans. Such projects are attempting to address the impacts of higher human population growth rates that result in the development of economies which in turn demand increasingly greater use of natural resources to produce viable communities. The ultimate result of all of these changes is that humans are leaving a much larger "ecological footprint" on the land-base and making it more difficult to practice conservation. This is especially relevant in landscapes experiencing higher deforestation rates.

One aspect of a higher deforestation concomitant with larger ecological footprint has been a reduction in ecological legacies. The influence of ecological legacies on species survival is often not accounted for in current conservation management, because many policy decisions have been based on science collected in non-legacy ecosystems. However, it is important for conservation management to account for ecological legacies, because of their influence on ecosystem function, including how ecosystems respond to disturbance events. Contemporary conservation efforts can incorporate ecological legacies into management planning by identifying and conserving factors that contribute to the formation of

Table 1 Summary of pre-1990 and post-1990 practices used to implement conservation efforts

	<i>Pre-1990 practices</i>	<i>Post-1990 practices</i>
Conservation focus	Single species based approach. <i>Ex situ</i> conservation for single species (e.g., zoos, expensive reintroduction programs, captive breeding programs).	Umbrella species approach. Ecosystem based. <i>In situ</i> conservation model preferred. Restoration of species and ecosystems, elimination of invasive species linked to conservation failures.
Integration of humans and human impacts on ecosystems in conservation	Protected areas management or reserves could be designed to exclude humans. Conservation practices strongly based on managing spatial distribution of ecosystems or habitat scales in landscapes since the major human impact has been fragmentation and loss of ecosystems.	Conservation is human ecosystem based – explicit integration of people as primary drivers of the success of protected areas or reserve management and a need for people to access conservation areas. Recognition of the temporal scales of human land-use activities and how they produce legacy ecosystems and landscapes that control the success of protected areas or reserves needed in conservation (states that few nonhuman-impacted ecosystems exist).
Human values	Species values dominant and used to drive conservation practices. Incorporate short-frequency disturbances.	Recognize species is one of multiple values existing in a system and a species focus may miss the “real” driving variables determining whether an established protected area or reserve will be successful. Incorporation of and determining trade-offs of all values desired out of a land as part of conservation. Inclusion of decade-scale disturbances (e.g., hurricanes) for species conservation.
Disturbances	Conservation plan to exclude or limit human extraction of resources from nature reserves. Humans classified as disturbance agents who are negative to conservation efforts. Reserve design and size varied with territory needs of each species. Landscape matrix analysis recognizing influences outside of habitat fragment will impact conservation.	Conservation plan includes human extraction of resources from nature reserves. Explicitly integrates invasive species as a major disturbance factor affecting conservation success. Reserve design and size based on the ecosystem and landscape and not on species territory needs. Recognition that linking habitat fragments with corridors is inadequate.
Spatial scale of analysis	Identify edge and interior regions of reserves and their influence on species composition. Assumed ability to transfer data from plot to produce regional maps of endangered species. Use of corridors and buffer zones to link habitat fragments and reserve networks. Reserve design focus – single large or several small, its size, where to place it.	Knowledge that human land-use legacies and disturbances modify edge and interior habitat quality. Inability to transfer plot data to produce regional maps of endangered species unless characterizes ecosystems into their diverse types within a vegetative community. Explicit link to GIS or remote sensing tools to integrate lessons learned from localized research sites.
Models	Small-scale, data-intensive species and community models.	Large-scale biodiversity models linked to spatial analysis tools under a climate change envelop. Ecosystem models geared to predicting human land-use activities and the sustainability of the ecosystems needed for conservation under a climate change envelop. Use of multi-objective decision-making models to assess trade-offs between conservation and sustainable development.
Economic evaluation	Development of nonmarket values for species.	Need to address all the values in each environment. Recognition that conservation efforts should not be driven just by economic analyses. Recognition that every landscape has multi-objectives and values compete so trade-offs need to be made.

legacy systems. Some factors contributing to the formation of legacy systems are:

- Past land uses and management practices, by fragmenting the conservation landscape and changing species composition, may be unable to provide sufficient and suitable habitat for species surviving in that landscape. For example, the insufficiency of habitat area for managing threatened grizzly bears has been well documented for the Greater Yellowstone Ecosystem. In this case, the logical approach would be to restore a sufficient area of suitable habitat for the grizzly bear. However, habitat alone will not ensure grizzly bears' survival since an exotic fungus is causing the decline of *Pinus albicaulis* whose seeds are an important food source for bears. This underscores the need to recognize that conservation efforts are complicated by other factors regulating the functioning of a system that are not considered because they do not appear to have a direct bearing on a species.
- Introduction of invasive plant species that alters the function of ecosystems, so they are less conducive for native species to grow. In Hawaii, an invasive nitrogen-fixing plant changed the abiotic soil environment of the newly invaded ecosystem or warm-season grasses arrested succession, thus the native species were unable to grow. Forest invasions by perennial grasses have been shown to increase the frequency and intensity of fire disturbances and thus shift the annual timing of these events. Invasive trees on forested watersheds have been known to transpire much more water than native trees, significantly altering forest hydrology.
- Existence of disturbances (e.g., hurricanes) that affect succession occurring at longer temporal frequencies than a manager's typical time frame. Recently the ecologists have come to understand the importance of disturbances that occur at long time frequencies (e.g., hurricanes) and how they affect the structure and drive the functioning of a system. Knowledge of these temporal dynamics is relevant for conservation, since the design of conservation efforts based only on consideration of intervals between disturbances can endanger an already threatened species. For example, when Hurricane Hugo swept over the tropical forests on Puerto Rico, the already small population of Puerto Rican parrots was dramatically reduced while the amphibian populations increased significantly. These hurricanes are a reoccurring phenomenon there and have been recorded at a frequency of 21 years. The effect of these hurricanes on determining the structure and functioning of these forests during the intervals between hurricanes is well documented. Consequently, if ecosystem processes are studied only during the inter-disturbance intervals, we may overlook the important causal drivers for that system.

Analysis of Evolving Thinking in Conservation Biology

Species to Ecosystem Shift

Because of the historical emphasis on saving threatened and endangered species, conservation biology has had a largely

singular focus on protecting those species and their habitats. This focus was found on a simple ethic that humankind has a moral obligation to protect all living things on the earth. This species-centric ethos seemed to be relevant in the early phase of conservation because anthropogenic changes to the land base were geographically localized. However, current approaches in conservation are strongly based on the ecosystem, landscape, and human system. This shift resulted because of the failure of many conservation efforts that were based on the protection of species. Yet it is important to recognize that the single-species approach should not be eliminated from the suite of tools available in conservation in the push to assess systems more holistically.

In some ecosystems, the single-species approach will continue to be a powerful tool for conservation biologists. For example, the single-species approach may still be appropriate as a primary conservation tool when a single species functions as a keystone species, an ecosystem engineer, or an umbrella species or a coarse-filter. In some ecosystems, keystone species can play an essential role in regulating ecosystem structure or function, and the maintenance of community diversity. In the event that keystone species are lost from the system, the result may be a disproportionately larger effect on some property of the system so that certain species can no longer survive in the landscape. However, the concept of keystones may be difficult to apply in conservation because these species are not always obvious or we have not developed a clear mechanism for identifying them in the system, and some are only keystones part of the time and under certain habitat conditions. Once keystone species have been identified, the ability to use the single-species approach simplifies conservation efforts and facilitates integrating conservation with restoration efforts. When a single species has not been identified that provides a key structural or functional role, species are poor indicators of whether a system is going to degrade or if the habitat can be maintained for the species needing to be conserved.

The use of a single-species focus in conservation is greatly facilitated when species function as ecosystem engineers. In any ecosystem, the existence of ecosystem engineers is easy to recognize because they modify some structural part of the ecosystem that can be readily detected. They do not have to be present in large numbers for the impact to be registered. In many examples, a few individuals will have a disproportionately large impact on directly changing plant successional processes and indirectly modifying carbon and nutrient cycles (as has been documented for beavers and moose). In addition, ecosystem engineers may play keystone roles at particular stages of the development of a vegetative community (i.e., their impact would not be measurable at all times).

In conservation biology, an important concept that has been discussed for more than a decade is the identification of single species that can function as an umbrella species or a coarse-filter. Umbrella species are those species that have large habitat needs (e.g., spotted owl, red-cockaded woodpecker, and grizzly bear) or have other requirements such that when the system is managed to conserve that species, many other species will consequently also be conserved. The single-species approach has been most often justified through the concept of umbrella species.

Unfortunately, many ecosystems do not have a single species that can be monitored to provide an indication of how that system is functioning and whether a conservation project will be successful. Based on our current scientific understanding, many species are merely passive inhabitants of ecosystem in which they live. Instead, entire communities of species may play integral roles in ecosystem function. Biodiversity may then be a critical determinant of ecosystem productivity and stability—including the tendency to resist anthropogenic impacts and the ability to recover from impacts (i.e., resilience). However, the relationships between biodiversity and ecosystem productivity or stability cannot be generalized to all ecosystems. Strong relationships between these variables have been found in certain ecosystems (e.g., grasslands), but biodiversity cannot be automatically used as an indicator of the ecosystem integrity. For example, the biodiversity at the species level is a poor indicator of the resistance and resilience characteristics of many forests to disturbances since the response of the system occurs at levels other than species diversity (e.g., genetic diversity within a species).

The growing realization that biodiversity may be inextricably linked to ecosystem function has given rise to a more holistic, system-centric perspective for conservation, now known as ecosystem management. This new approach was codified in 1996 by Mangel and others, when they defined a set of principles to which conservationists must adhere to successfully conserve wild living beings. The principles of ecosystem management are:

- (1) Focus on the sustainability of ecosystems, not on the output of products; (2) Adopt a holistic understanding of the way all the parts are linked together in an ecosystem and the feedbacks among those linkages; (3) Incorporate a long-term perspective and examine issues at a scale relevant to the functioning of the ecosystem; and (4) Recognize that human values shape ecosystem structure and function in myriad ways that can constrain, promote, or reduce sustainability.

Because the primary goal of conservation is to sustain the habitat or ecosystem where species live, conservation biologists have already espoused the first principle of ecosystem management as articulated here. Most of the tools developed in conservation biology address this first principle but not the other three principles. Similar to what is still happening in ecosystem management, conservation biologists are currently assessing the practicality of the different tools to implement the other three principles in conservation. Out of the four principles listed here, the incorporation of people and their values into a holistic framework of analysis that is not solely human-oriented is one of the greatest challenges for both ecosystem management and conservation.

Contemporary conservation also faces similar challenges to those previously experienced by natural resource managers attempting to implement ecosystem management under conditions of high scientific uncertainty. For example, natural resource management shifted from a resource-based emphasis (e.g., forest stands, fish stocks) to a more holistic, ecosystem-based approach that better enfranchises all stakeholders of a particular land or resource base. In the face of such a shift, managers were forced to embrace new management models

(i.e., adaptive management) to deal with large-scale management problems under a scenario of high scientific uncertainty about the response of ecosystems to human activities. Because our scientific knowledge base is still fairly limited, few guidelines exist to help resolve conflicts arising from the need to determine the tradeoffs between different natural resource uses. These conflicts are especially difficult to resolve since conservation biologists and ecosystem managers have to deal with resource scarcities.

The current view of Gordon is that ecosystem and adaptive management are both approaches attempting to respond to resource scarcities. Ecosystem management is attempting to respond to a scarcity of land. This land scarcity means that the exclusive uses of any given land area for one purpose is no longer possible because the production capacities of ecosystems are finite. This contrasts with adaptive management, in which managers are responding to scarcity of scientific information and knowledge. This scarcity makes it difficult to develop consensus on which tools are most appropriate to use for resolving the conflicts over resource uses. In a similar vein, conservation biologists are being forced to respond to scarcity and the resulting conflicts that can arise over the use of finite resources. However, conservation has yet to adopt a model that can adequately handle conflicts resulting from the scarcity of resources and simultaneously achieve natural and social system sustainability.

Direct and Indirect Influences of Humans on Conservation Efforts

Humans are strong influences on whether conservation projects are successful. A major deterrent to conservation has been the inability of most governments to satisfy all the resource uses, services, and values that are expected from the same land base by local, regional, national, and international stakeholders. Under these circumstances, the scarcity of land area and resources often results in conflicts over the uses of natural resources that typically polarize the people inhabiting the environment against conservation organizations articulating a need to establish reserves to save species. These conflicts often occur in environments where the land base constraints the options that are available to satisfy all the needs of all stakeholders. Some of the direct impacts of humans on the environment appear to be easier to manage, since alternative solutions are possible through substitution of products, technological breakthroughs that make resource extraction more efficient, shifting to the use of different resources, alternative employment opportunities, and so on.

Some of the direct and indirect impacts of humans are much more difficult to manage in conservation since we are just beginning to understand these effects. Many of these effects occur at longer temporal and spatial scales, making it more difficult to explicitly link the cause-and-effect relationships needed to identify the tools which will indicate when changes to species and ecosystems may occur. The impacts of humans on species loss and changing ecosystem structure and function will be further discussed next, especially as it relates to sustainable development.

Humans and Sustainable Development as an Integral Part of the Conservation Formula

Within the last two decades, there has been an increasing understanding that conservation projects cannot be successful when implemented in isolation from neighboring human populations. Management of nature reserves has undergone a major strategy shift from trying to keep people out of reserves to allowing some economic development by local communities as an integral part of the conservation strategy. The response of the international community to deal with this issue has been to design projects that explicitly link international aid to local communities to the establishment of nature reserves to conserve species. The goal of these projects has been to improve the livelihood of people living close to the natural resources so that they would not be dependent on extracting species or resources from the protected area. The strategy behind this approach was to find a balance between development and conservation by providing alternative approaches for people to survive and at the same time provide zones of lower human impact for conservation purposes.

This ecosystem-based model of conservation attempts to reconcile human pressures on resources in areas rich in biodiversity and those identified as high priority areas for conservation. This represents a major shift from the traditional conservation model, whose main focus was to lock up resources by removing humans already living in nature reserves without considering how these communities would continue to survive when denied access to these areas. Conservationists now recognize that successful conservation efforts will require explicit recognition and alleviation of human dependence on natural resources at the local level. It has become quite apparent that it was insufficient to demarcate parks and assume that people with few options would stay out of these areas.

In fact, humans have had an integral hand in shaping many of the landscapes and ecosystems that we now wish to conserve. It is important to recognize that present forest conditions may be strongly influenced by management and land use activities of the indigenous and rural communities. Thus by eliminating indigenous land managers from the landscape will likely alter the forest composition to a state unacceptable or undesirable for conservation purposes. For instance in wet tropical forests, humans have strongly influenced the resident biodiversity; indeed, the "virgin forests" and exceptionally rich biodiversity that are the focus of conservation efforts in the Amazon River basin are in part relicts of old agricultural practices and management.

The importance of the human dimension was especially reinforced for conservationists working in the tropics, where desperate people continued to harvest resources from forests set aside as nature reserves. Many of the conservation organizations funding the establishment of protected areas quickly recognized that nature reserves could not be maintained if they were designed to exclude local communities without providing alternative sources of income. This recognition stimulated the development of conservation and sustainable development projects called Integrated Conservation and Development Project (ICDP) which will be further discussed in the Section, Economic Evaluations and Conservation Trade-offs with Competing Resource Demands. Most of the current projects designed to conserve biodiversity are encouraging

local communities to use areas outside of reserves or at least outside of the core conservation zones. This strategy resembles the UNESCO Man and the Biosphere (MAB) design for reserves, which is based on having concentric zones representing different intensities of human use—with the center or core area designated for conservation without human presence. However, shifting or confining people's use of forest to particular zones without their cooperation is impossible in most developing countries. Often, land tenure or ownership does not exist for these local communities but they are still dependent on extracting resources from these same lands for their survival. Furthermore, these communities are accustomed to adjusting their resource acquisition efforts within the landscape both seasonally and by migrating to different locations.

In more industrialized countries, conservation organizations historically did not have to deal with indigenous or rural communities. The reason for this is that newly designated conservation areas had already mostly excluded or removed communities who lived and survived off the natural resources contained on these lands. However, this does not mean that the more industrialized countries do not incorporate the human dimensions into conservation; rather indigenous people have not driven the approaches being used in conservation. For example, Native Americans used fire to maintain grasslands for ungulates or to manage forests to increase the dominance of trees with cultural value such as cedar or pines. However, when parks were originally established in present day US, wildfire control was the accepted practice and fire was not deemed as an appropriate park management tool.

In stark contrast to the less industrialized countries, industrialized countries have placed greater emphasis on developing the tools to protect and restore habitats and species, and in eradicating invasive species that threaten indigenous non-human species composition and alter succession. The spread of invasive species and the concomitant loss of indigenous species is a problem driven by international trade and the globalization of world trade. The changing transportation networks and development of a global economy are contributing to an accelerated rate of the spread of invasive species that has not been documented prior to this time. In addition, the spread of invasive species frequently occurs in ecosystems that have been significantly modified by human land-use activities and few good control mechanisms have been produced. Humans have been modifying their environments at unprecedented rates during the last several decades. Because of the role that humans are playing in spreading species and in altering the health of ecosystems, one of the greatest challenges to the successful implementation of conservation projects may be our ability to control the spread of invasive species. The impact of invasive species on conservation efforts is further discussed in the next section.

Humans and Invasive Species

Within the last two decades, many conservation organizations have implemented programs to reduce or eradicate exotic invasive species. This was driven by numerous cases of invasive species disrupting or altering native ecosystem functions and structures, as well as reducing regional biodiversity. The significant economic costs of controlling invasive species divert resources from other areas of biological conservation. Invasive

species challenge conservation efforts because they limit the options available for the conservation of indigenous species and their intact ecosystems. The spread of invasive species will probably become more critical in the future as humans create conditions or change disturbance cycles sufficiently to give invasive species the opportunity to dominate more habitats. Climate change is also expected to increase the ability of invasive species to spread into landscapes under duress (see the Section, Contemporary Conservation and Climate Change).

Humans have played a dominant role in the spread of invasive species around the world. Humans function as vectors of invasive species and alter the landscape in a way that enables invasive species to become better competitors than native species. Many weeds, insects, and other animal pests are transported accidentally with produce and goods; food crops and horticultural varieties are often introduced to new environments intentionally for agriculture and landscaping. Likewise, there is a long history of humans introducing game animals to new territories. Species already associated with areas of human development are consequently more likely to be introduced to new areas by human vectors, and the areas to which they are introduced tend to be more readily overwhelmed. Observations suggest that alien plant species richness correlates positively with proximity to human development and transport centers. For example, stocks of seed and produce shipped overseas often carry with them seeds of many weed species that germinate in their new environment. These shipments commonly include alien microbes and animal pests as well. Intentional introductions of species imported for agriculture and other human uses are common, as are introductions of organisms employed as biological control agents to stanch the tide of previously introduced and invasive species. Today, the production of biofuels using grasses is stimulating new concerns that potentially invasive plants will be introduced to areas where grasses have not previously grown and where they are more competitive compared to native species.

Although the invasion of ecosystems by alien species certainly has occurred throughout human history, the problems of alien invasion remain particularly challenging both for scientists studying patterns and processes of invasion and ecosystem managers attempting to eradicate or control invaders. In many parts of the world, particularly on islands, even the greatest conservation efforts are ineffective at countering the proliferation of exotic species. Where invaders are well established, such as rats in New Zealand and *melastome* plants in Hawaii, invasive species are nearly impossible to control and conservation strategies need to explicitly manage invasive species that currently cannot be eliminated. In less severe cases, conservation practices may be able to protect biodiversity and limit the establishment and spread of exotic species.

Because of the uncertainty in our understanding of invasive species, conservation biologists will have to consider whether invasive species are present in areas targeted for conservation. If invasive species are present, it will be important to consult the biological literature and determine whether and what types of effects may be attributed to that invasive species. If these invasive species are shown to negatively affect indigenous species and ecosystems, it will be critical to eradicate small

pockets of invasive species when they are found to prevent their establishment and spread to the point where they cannot be controlled. This suggests that conservation practices will have to aggressively manage invasive species even when their impacts have not been conclusively shown to detrimentally affect the target system. It will be critical for conservation to establish priorities and develop an effective strategy for preventing and handling invasive species.

Tools for Managing and Conserving Species

When Michael Soulé, the “father of conservation biology,” was interviewed in 1994 and asked about the developments in conservation biology in the last decade, he pointed out that there has not been a revolution in how conservation biology is practiced. Rather, he stated that conservation has been experiencing a gradual refinement in the principles and tools of the field. Soulé suggested that the major tools have been the application of theory from the fields of island biogeography, population biology, and community ecology, namely, consideration of the matrix landscape within which a habitat is embedded, development of biological corridors, development of new tools in molecular biology, and development of integrated population viability analysis frameworks that include demographic, environmental, and genetic stochasticity. All of these are commonly still used in conservation today.

Since the early 1990s, however, there has been a revolution in the philosophical basis of conservation biology. As discussed earlier, five philosophical changes have occurred in conservation; however, two have arisen to the forefront of discussions during the last two decades. These two philosophical changes have also been the most difficult to convert into practical applications for natural resource management. One is the acceptance of the ecosystem approach as the management tool to resolve conflicts arising from the public perception that communal lands are poorly managed and not conserving biodiversity. The second philosophical change is the acknowledgment of the importance of human dimensions in natural resource management. Because both philosophical changes determine what tools and approaches to use in conservation, they have made the science and practice of conservation more challenging and have required conservation biologists to make more complicated and difficult choices. For the purposes of this review we define conservation approaches as specific frameworks or underlying structures used to benefit biodiversity indirectly, and conservation tools as devices or processes designed to benefit biodiversity directly. Contemporary conservation tools and approaches will be explored next.

Contemporary Conservation Tools and Approaches

Based on discussions in the Sections, Introduction: New Concepts in Conservation and Analysis of Evolving Thinking in Conservation Biology, it is easy to see that the practice of conservation has changed dramatically since its inception in the early twentieth century. In fact, conservation has evolved to such a great rate in recent decades that many of the

approaches, tools, and foci of contemporary conservation are largely different from those implemented 10 years ago. Yet, despite a number of broad and fundamental developments in the field of conservation, perhaps the clearest trend has been the shift away from the dominant approaches developed by early conservationists. Early conservation was primarily focused on the creation of parks for recreational and aesthetic reasons, and the conservation of a small number of species, particularly beautiful birds and enigmatic mammals. To achieve these objectives, such an approach to conservation developed tools that were effective at designing and monitoring.

However, over the course of the twentieth century, conservationists' focus has expanded from the objective of establishing beautiful parks and conserving select species towards a more holistic goal of ecosystem integrity; a goal that goes well beyond the conservation of individual species and beautiful landscapes to include the protection of the existing diversity of species, natural habitats, and ecosystem processes. While protecting particular species and areas of outstanding natural beauty remain an element of contemporary conservation, advocates for the protection of ecosystem integrity argue that a focus on single species or beautiful landscapes inherently limits biodiversity conservation. In other words, to focus conservation efforts solely on a limited number of species makes the conservation of earth's biodiversity almost impossible, as the sheer number of species and the lack of positive attention to many species (e.g., insects, snakes, fungi) leaves them and the ecosystems unprotected. Likewise, by focusing conservation efforts only on natural areas of high aesthetic value (e.g., temperate mountainous regions), other ecosystems critical to the continued provision of ecosystem and cultural services may be lost.

Taken together, as a result of these persuasive arguments and broader changes in thinking across the conservation movement, contemporary conservation has shifted its focus to protecting biodiversity in all its forms. One of the primary outcomes of this shift is the development of a host of new tools and approaches to achieve conservation. These developments have undoubtedly improved the efficacy and efficiency of conservation, but they have not eliminated conservationists' need to answer fundamental questions about their goals and strategies, particularly (1) What biodiversity should be conserved; e.g., should the focus be particular species, ecosystems, or ecosystem services? (2) Where does the targeted biodiversity occur, and where is the best place to protect it? and (3) Given the variety of conservation tools available, which is the most effective method to achieve conservation objectives? Each of these questions should be asked by a conservation planner because they require managers to address the key elements and challenges integral to the development of an ecosystem-based toolkit to guide conservation efforts. These questions are often difficult to solve, but they cannot remain unanswered, as they provide essential guidance to conservation efforts. And while the science of conservation has matured dramatically over the last few decades, the field of conservation still remains immature, leaving conservationists to work with a body of knowledge and set of tools that remain incomplete. However, despite a limited understanding of how conservation efforts interact with

surrounding socio-environmental systems, the field of conservation has amassed an impressive base of knowledge, as well as a robust set of tools and approaches to achieve its goals.

Identifying Biodiversity Conservation Goals

In recent decades, the field of conservation has coalesced around three overarching methods for conserving and protecting biodiversity: (1) *in situ* conservation (i.e., onsite conservation), (2) *ex situ* conservation (i.e., offsite conservation), and (3) restoration (i.e., the reestablishment of native species and ecosystems). With the growing depth of conservation science in mind, we now turn to the prominent conservation approaches and tools used in *in situ* conservation.

When conservationists focus on *in situ* activities the first important question they often face is "what biodiversity should be conserved?" Among the many options available to answer this question, one of the more prominent methods used is known as the "hotspots" approach. The concept of biological hotspots, originally developed by Myers, is designed to focus conservation efforts by identifying geographic regions with exceptionally high levels of species richness, endemism, or rarity. The hotspots approach has proven widely popular and has been embraced across a variety of conservation groups and initiatives, including the Critical Ecosystems Partnership Fund, whose members include Conservation International and the Global Environmental Facility, the Endemic Bird Areas initiative organized by Birdlife International, and the Global 200 Ecosystems initiative developed by World Wildlife Fund. Generally speaking, each hotspot initiative generates maps and strategies to prioritize conservation efforts for ecosystems with exceptionally high levels of biodiversity, and depending on the hotspot methodology used, areas defined as hotspots have undergone a substantial loss of habitat and face growing threats from human disturbance.

Another approach often used to define the focus of conservation efforts is known as the coarse-filter/fine-filter approach that was originally developed by the US Nature Conservancy. The coarse-filter/fine-filter approach is designed to achieve biodiversity conservation by ensuring that a given landscape's naturally occurring species and ecological communities are protected. At its most basic, the coarse-filter approach is a broad scale analysis designed to identify and protect existing plant and animal communities, whereas, the fine-filter approach is used to complement the coarse-filter approach by identifying individual species, features, or processes missed by the coarse-filter analysis. Together, the coarse-filter/fine-filter approach enables conservationists to protect representative samples of native species, plant and animal communities, and ecosystem processes occurring across a targeted landscape, while ensuring that conservation activities include unique or underrepresented species and features.

Designing and managing conservation networks using the coarse-filter/fine-filter approach has become commonplace in many organizations involved in conservation efforts across the US and beyond, including land management agencies, such as the US Forest Service, large conservation organizations, particularly the Nature Conservancy, and a variety of small conservation groups, including many local land trusts. Conservationists frequently use the hotspot approach or the

coarse-filter/fine-filter approach, but in other cases conservation priorities are determined by existing species, ecosystems, or ecosystem services, as well as undeveloped green spaces, or cultural and historic features.

After conservation priorities have been determined, the next set of questions often includes, “where does the targeted biodiversity occur, and where is the best place to protect it?” By asking this question, scale considerations will become the focus of a conservation planner. Today, the shift from conserving species to an ecosystem-based approach complicates the demarcation of the habitat borders and the extent of land area needed by conservation projects. Because identifying the scale needed to protect biodiversity is critical, a brief discussion is given of the evolution of our approach to species and scale before the ecosystem approach began to dominate.

Identifying the Appropriate Conservation Landscape Scale *Species-Based Conservation Scale*

Much of the original theoretical work by conservation biologists was based on determining the relationships between species and their space (as first articulated by MacArthur and Wilson). The suggestion that habitat area was positively correlated to species richness provided arguments for designing larger natural reserve areas for maximizing the conservation of species. The size of a reserve area needed for effective conservation has been argued in the literature for more than 20 years without the development of a consensus. Part of the reason for a lack of consensus is that we know that area by itself is insufficient to characterize how many species can be maintained at a site.

Even though space has been an important theoretical issue in conservation, the practical application of theory in conservation appears to have no dominant spatial scale of analysis. Therefore, theories and applications have not been linked at the spatial scale. A lack of defined spatial scale in applied conservation has been strongly influenced by the focus on specific animals as important species to conserve. The spatial scale at which conservation has been practiced has varied according to the territorial needs of the species of interest. This trend is apparent from a survey of key journals published in 1998 by Vogt and others who tabulated the scales of analysis used by conservation biologists, community and population ecologists, and social ecologists. An amazingly high proportion of the articles published in the journal *Conservation Biology* did not even present the scale being used in the study; this suggests that spatial scale was not considered relevant by the authors for understanding their system. When a scale of analysis was presented, the smallest scale (<0.01 ha) was as equally represented as the largest scale ($>10,000$ ha). Again, this reflects the focus on animals with different habitat area requirements.

This contrasts with much of the information collected from community and population ecology journals, where small-scale research is predominantly used to understand species relationships to ecosystem parameters. For example, plant ecologists who developed the theory behind species dynamics focused on scales that were less than 0.01 ha in size. Some studies are being conducted at larger scales, but these larger scales of analyses are applied in the tropics and are less

common in other regions of the world. In the humid tropics, the presence of rare plant species has necessitated the establishment of permanent plots that are 50 ha in size.

Furthermore, because conservation biologists have accepted the ecosystem management paradigm, many more scales of analyses are included in conservation. For example, the watershed has been accepted as the relevant scale in ecosystem management, for it includes the drainage of a freshwater footprint of a bounded-land area. In ecosystem management, the watershed defines the scale and boundaries of interaction of the social and natural environments. A watershed scale is only one of the many scales that could be used in conservation but it will only be the appropriate scale for some animals, e.g., small, non-migrating animals. Selecting one scale of analysis for all systems is problematic because scale is site dependent and must be chosen to reflect the driving variables controlling the functioning and resilience of that system.

Landscape Ecosystem-Based Conservation Scale

Today, there are a number of ways to identify and prioritize the location of conservation efforts using the ecosystem approach, including “gap analysis,” site selection algorithms, and expert opinion. A gap analysis is a spatial tool used for conservation planning designed to identify conservation gaps in conservation areas. The objective of the gap analysis is similar to the coarse-filter/fine-filter approach in that it seeks to ensure that all components of biodiversity on a given landscape are included in conservation areas. In addition to the gap approach, soliciting expert opinion and using site selection algorithms or a combination of expert opinion and site selection algorithms can be used for reserve planning and expansion. Experts can range from local community members familiar with the location of local flora and fauna to research scientists and land managers. Generally, site selection algorithms tend to result in more cost efficient conservation networks, as they tend to rely on objective measures, such as the price of land parcels. However, few algorithms have been used in applied conservation because of their complexity. Nevertheless, a combination of expert knowledge and algorithms may result in robust conservation planning, especially in areas with limited or non-existent datasets.

The selection of specific sites to focus conservation efforts is essential to the practice of conservation, but site selection is not limited to small geographic areas. Rather, because many areas of natural habitat are often islands in large seas of human landscapes, one emerging approach to focusing conservation efforts is to ensure landscape connectivity between protected areas. To connect dispersed conservation areas into an integrated conservation network, often termed landscape-scale conservation, conservationists work to identify the best locations to create habitat corridors and enlarge protected areas. A common underlying goal of this approach is to increase habitat connectivity for species that require large areas of continuous habitat, such as many large mammals and migratory species. Additionally, another catalyst for the push to connect natural habitats across large geographic areas is the emergence of climate change as an increasing threat to biodiversity. Put simply, as the global climate continues to

warm, many species will be forced to migrate to more suitable habitats, but if the habitats they need are inaccessible, the likelihood of their extirpation or extinction is magnified (see the Section, Contemporary Conservation and Climate Change).

Today, landscape-scale conservation initiatives are becoming a popular approach to conservation, and numerous projects are underway around the world. One innovative proposal known as the Sky Islands Wilderness Network (SIWN) seeks to conserve and connect natural habitats across forty arid mountain ranges of the American Southwest and northern Mexico. Another proposal in North America, even larger than the SIWN, is a plan to link habitat from Yellowstone National Park in the US to the northern Yukon region of Canada. This ambitious plan, known as the “Yellowstone to Yukon” initiative, aims to ensure connectivity between lands spread across more than 1.3 million square kilometres. Another ambitious landscape-scale proposal worthy of note is the proposed Mesoamerican Corridor in Central America, which is designed to create a continuous habitat corridor between parks in southern Mexico to other protected areas throughout Central America (Trombulak and Baldwin, 2010). The bulk of these plans are on public lands where landscape scale initiatives are easier to implement in contrast to private lands because of their competing and often conflicting land-use objectives. The long-term goal of these projects is to expand the conservation value of public lands by buying private lands when these lands become available to increase the landscape connectivity for biodiversity.

Conservationists now generally agree that landscape-scale approaches are essential to conserve biodiversity. Arguably the greatest challenge facing many landscape-scale conservation initiatives is managing a greater number of complex issues than those typically faced in smaller conservation projects. Increased complexity for larger landscape-scale projects stems largely from the greater diversity of human demands and governance structures inherent across larger areas. However, given that the core challenge of conservation is ultimately about managing people, the fundamental focus of conservation is often remarkably similar across both large and small scale conservation projects. So whether conservation efforts are focused on a small city park or across vast heterogeneous landscape, conservationists must ultimately confront the needs and preferences of people and balance them with the needs of biodiversity. In considering the many challenges inherent in balancing competing needs, the third and perhaps the most important question facing the practice of conservation is “given the variety of conservation tools available, what is

most effective method to achieve conservation?” This question will be briefly discussed next.

Need for Multiple Conservation Operational Tools

From establishing parks to enacting environmental legislation, policy-makers and conservationists have a wide variety of conservation tools available to them. Yet, while there are many possible options, no tool is a “silver bullet” because contextual factors are highly variable across time and space. Contextual factors most pertinent to the effectiveness of conservation tools include: political and financial considerations, the specificities of the conservation target, and institutional capacity for implementing conservation strategies. Also, the sheer number of tools available can create difficulties in selecting the most appropriate tool for each situation. In short, determining the right tool to achieve conservation objectives can be difficult.

To simplify the selection process, it is helpful to evaluate available options based on the operational theories underlying the development and implementation of each tool. By using operational theories as a guide, conservation tools can be organized into three categories: (1) *Governance-based* tools, (2) *Market-based* tools, and (3) *Civil society-based* tools (see Table 2). These are summarized below:

Governance-based tools are often premised on the assumption that conservation objectives are most *effectively* achieved when developed and conducted by a government – local, regional, or national. The effectiveness of these tools is thought to stem from the inherent powers vested in governments to create and enforce the rule of law. Governance-based tools are often defined as a “top-down” or “command-and-control” approaches to conservation.

Market-based tools are commonly identified as the most *efficient* approach to conservation. Market-based tools are believed to be efficient because they are designed to use cost advantages often achieved through the practice of free market economics. Market-based tools are sometimes described as “free-market” approaches to conservation. Market-based approaches can achieve conservation goals because people generally act in their own self-interest. Given this reality, a host of tools have been developed to incentivize human actions that also benefit biodiversity.

Civil society-based tools are often considered to be the most *durable* conservation solutions because they are found on the strength of civic consensus and democratic principles. The tools of civil society embrace a wide variety of methods developed and implemented by individual citizens and civic organizations. These tools are often defined as a “bottom-up approach” to conservation.

Table 2 The three categories of tools and how they have been implemented in conservation landscapes

<i>Governance-based approaches</i>	<i>Market-based approaches</i>	<i>Civil Society-based approaches</i>
Parks, domestic regulations and legislation, international treaties, criminal prosecution and fines, debt-for-nature swaps, species reintroduction, and management	Payment for environmental services, forest products certification, sustainable products, ecotourism, and conservation investment banking	Privately owned parks, civil suits, media and education campaigns, civil disobedience, conservation easements, backyard habitat areas, and fundraising and grant-making

Economic Evaluations and Conservation Trade-offs with Competing Resource Demands

In the past, economics was the dominant tool used to build a market-based rationale for conserving species and ecosystems. Economics was used to assess whether conservation, and the resulting protection of ecosystem services, is more valuable than extraction or harvesting of resources. However, this overreliance on economics as the primary tool to build a rationale for conservation has produced mixed results. It has been extremely difficult for economists to provide a monetary value to non-market goods obtained from an ecosystem, such as clean water, or to value goods that are locally traded but where there is no transfer of money. This quandary is apparent from the brief discussion that follows of how economic evaluation developed as an approach to link conservation with sustainable development.

In the late 1980s, the need to address the trade-offs between conservation and the sustainable livelihoods of communities living in the same tropical landscape, conservation biologists and economists began to combine their expertise to make conservation efforts more robust. Because these rural communities were dependent on resource extraction to survive, they needed new economic opportunities to replace the resources to which they no longer had access when their traditional resource gathering grounds were placed under protected status. These economic analyses suggested several options for generating income for rural communities, but mostly they suggested producing economic value for previously non-market-valued products.

Historically, tropical forests had been undervalued when only timber and agricultural uses were used to estimate their net worth, so that there was no clear economic incentive to conserve these forests. If market-value could be generated for non-timber forest products, it would diversify the economic options for rural communities while maintaining habitats for species. Economists had suggested that the lack of proper economic valuation had contributed to accelerating the rate of harvesting and conversion of forests for other uses. Therefore, a tactic to decrease deforestation rates was to determine the “real” value of the forest by including all other products that could be extracted from it (e.g., non-timber forest products and services like watershed protection). Using an ecosystem based economic analysis, the forest was no longer undervalued, and alternative products could be extracted that would provide income to local communities. This strategy was widely promoted by the international development community to conserve forests and biodiversity in reserves while also generating income for local communities from the same reserve or surrounding areas.

A strategy of combining conservation with sustainable development, as previously discussed and known as ICDP, was supported by economic studies reporting that the extraction of non-timber forest products would return greater value in the marketplace than timber harvesting. In addition, this approach was promoted as a new alternative to reduce the dependence of the local community on natural resources that were being protected in a newly formed conservation area. International funding organizations were interested in developing these non-market values from forests because it

suggested that the goals of conservation were compatible with developing an economic base for local communities. The idea was that local communities could forgo harvesting some resources (trees, wildlife, etc.) within designated reserve areas if sufficient income could be generated from pursuing alternative income generating activities in the same forest. As part of the new ICDP approach that began in the 1990s, ecotourism and the harvesting of non-timber forest products were presented as two viable alternatives for local communities to generate income. However, these options have not as yet proven to be effective in meeting the dual goals of biodiversity conservation and rural economic development. Unfortunately, it is not clear whether the goals of conservation and sustainable development are compatible under this rubric. Dove and others have conducted research suggesting that this strategy should be approached with caution, for developing a total value for a forest does not protect it from being overharvested.

Some economic analyses have been criticized for producing unrealistic expectations of the value of what can be sustainably extracted from a forest. These earlier economic analyses used biological inventory data to calculate an optimal amount of non-timber forest resources to be collected and the potential economic value of harvesting non-timber forest resources. These economic analyses did not consider the dependence of local communities on these same resources for their survival or their role in maintaining ecosystem function or landscape biodiversity. Biological inventory data also do not indicate the amount of a product that can be harvested in an ecologically sound manner. These data produced results that significantly overestimated the expected income generated annually from extracting these products. Indeed, placing an economic value on a resource can increase the demand for that product so that it is quickly overharvested; when this occurs, the species may be lost from the landscape where it previously was quite common.

Conservation projects have also struggled with how to achieve the dual goals of conservation and maintenance of indigenous communities living in the same land. Frequently the species to be conserved was also an important food source for local communities. Therefore, rural communities were perceived to be a threat to conservation. There are abundant examples from around the world of the competing objectives causing strife between conservationists and rural communities. This has made it difficult for conservationists to balance the goals of conservation projects with the continued presence of indigenous communities living on these same lands. This inability to make choices, and the assumption that these communities threatened conservation efficacy, drove the forced removal of indigenous communities from their traditional lands. These people have been called ‘conservation refugees’. For the indigenous communities, the consequences were dire. This loss of access to resources from their traditional lands caused them to become dependent on government subsidies to survive or to have few survival options because of the difficulty of adapting to landless based employment opportunities.

There is greater recognition today that alternative and diverse approaches are needed to increase the economic opportunities for local communities to become self-sustainable. Recent efforts to allow local communities to manage and

make the trade-off decisions on how resources are protected or consumed have facilitated local communities' contributions towards regional sustainability. For example, forest certification in Indonesia had the unintended consequence of facilitating indigenous communities to gain more control over managing and controlling resources on lands that they traditionally owned, i.e., today they have no land ownership rights for these lands. A new emerging trend in the US is for indigenous and rural communities to become stewards and comanagers of public lands for economic benefits and conservation even though they do not own these lands.

Conservation in Human Altered Landscapes

The solutions to the problems facing conservation biologists will not be found solely by adopting new paradigms such as ecosystem management or sustainable development. Blending the theories developed in conservation biology with these new paradigms will potentially allow for better management of species within their landscapes. However, conservation biologists will not automatically find the tools that they need from other disciplines. These new paradigms are currently struggling to develop tools that will be able to take theories and make them applicable to, for example, forest certification. Furthermore, conservation biologists have not developed structures similar to ecosystem management that would allow them to develop an adaptive management model (i.e., a way to allow scientific data to continuously modify policy links as better information became available). Without such a process or framework to effectively link policy to science and management, it is difficult to integrate scientific findings into management itself. As stated by Gordon in 1999, "Often, policy is made with 'old' science, while interest groups confront the manager of public resources with 'new' science." One could speculate that "old" science is used because the tools have not been developed to implement or make the "new" science work at the ground level or in policy.

Conservation biologists will also have to confront the fact that humans have altered the environment on a global scale. On this globe, it is difficult to find land that has not experienced some form of human land-use activity or extraction of resources. For example, 30 years ago scientists were shocked to find pollution generated in distant countries on glaciers in the European Alps. In many cases, the current ecosystem we want to conserve may be an artifact of past human activities. If this is not recognized, it may be extremely difficult to conserve species because we really do not understand the driving variables that may control the resistance and resilience characteristics of the system. As protected area managers are increasingly called upon to generate funds through development projects (e.g., ecotourism, timber harvest, and non-timber forest product extraction), it is important that one of the original goals of setting up these reserves as "genetic libraries" is not compromised.

Restoration is frequently suggested as a way to re-establish desired ecosystems and at the same time maintain the biodiversity of indigenous species and exclude the invasive species. This is especially relevant considering the problems that conservation managers are facing with invasive species and

altered landscapes. However, the science of restoration ecology is still evolving, and standard tools are not readily available for utilization by conservation biologists. A current practice has been to allow the development and elimination of a specific habitat with the assumption that an equivalent habitat will be recreated at another location. This approach has been commonly used in wetlands. Unfortunately, the successful restoration of a habitat that can then be used by an endangered species rarely results. For example, it is not unusual that a restored marsh that was supposed to support an endangered species was not suitable habitat for that species or did not support other species found in a reference marsh. Since restoration ecology is still a young science, it is not surprising that restoration tools still need to be tested in a variety of systems. Many restoration efforts are currently dealing with eradicating invasive species that have begun to dominate much of our landscape. Yet we have a minimal understanding of the impact of invasive species within landscapes and of the long-term ecological effects that they may exert in these newly modified environments.

Conservation biology has done well in developing the science of understanding individual species in their habitat, performing spatial scale analyses of individuals, and modeling their activity within the landscape. It has not done well in the following areas:

- Incorporating the roles and needs of humans in conservation situations, especially at the local level. The values and principles of national and international organizations have largely driven conservation efforts.
- Developing frameworks for moving beyond the species focus and incorporating the dynamic nature of ecosystems into these frameworks.
- Focusing on the use of "easy" tools (i.e., GIS models) has restricted the diversity of conservation approaches and created a dependence on a small set of tools, thereby excluding the use of a more varied and innovative suite of tools.
- Adapting conservation planning to future environmental (e.g., land conversion, loss of forests, loss of soil productive capacity, climate change, etc.) and social change (e.g., technology in converting bio-resources to new products, higher population density, increased industrialization of less developed countries, etc.).

One of the greatest challenges to conservation efficacy is climate change. It can potentially decrease environmental as well as social resilience since it is not clear how species will adapt to climate change and its altered disturbance cycles. This topic deserves further discussion because of its potential impact on conservation planning.

Contemporary Conservation and Climate Change

There are many potential impacts of climate change on the ecology of conservation landscapes. The predicted ecological consequences and impacts on biodiversity due to climate change include significant restructuring of coastal and estuarine systems, shifting species distributions (often hindered by habitat fragmentation or geographic isolation), as well as

significant changes in ecosystem processes including altered fire and hydrological cycles. Furthermore, temperature induced changes in plant phenology may disturb plant–pollinator relationships. In addition, temperature changes are also predicted to trigger trophic cascades, parasite and pathogen pandemics and general population declines especially of sensitive species. Most of these impacts will be expressed across larger landscape scales making it challenging for conservation planners managing at the scale of a reserve.

The most challenging impact of climate change may be the alteration of habitat area and quality needed by conservation projects. Species populations depend principally on the area of suitable habitat and the quality of this habitat. Therefore, conservation planning may need to include strategies to maintain and increase the areas of high quality habitats, prioritize centers of species endemism, and also prioritize areas that have high environmental heterogeneity. Maintaining conservation areas with fixed boundaries, however, is problematic given the vagaries of climate change. The artificial and even natural boundaries designating zones of conservation may be rendered obsolete by rising water tables, persistent droughts, and other climate induced alterations. Increasing the connectivity of conserved regions is a contemporary tool to hedge against the climatic realignments thereby providing conserved species a potential exit strategy.

Projected temperature changes may shift the ranges of diverse taxa poleward by an average of 61 km over the next hundred years. This distance is an order of magnitude larger than the average north-south extent of protected areas in North America. Therefore, this dramatic shift would require current conservation zones to be increased 10-fold, which is an unlikely situation given the challenges of implementing and managing conserved land. This projected increase assumes exiting conservation zones will remain habitable for many species which is a difficult assumption to make since many ecosystems are decreasing in area (e.g., tropical cloud forests) or no longer provide the refugia (e.g., Sky Islands of the south western US) for species due to land-use changes that are isolating ecosystems in a landscape.

Since climate change models address scales that are global or at regional scales, it may be difficult to justify using them in conservation planning being implemented at a local scale. For example, managers of parks or nature reserves may find it difficult to manage for changes in species distribution that may occur beyond their management area. In other cases, vegetation shifts along moisture gradients and temperature isoclines are predicted at large geographic scales, so the management area may only encompass a small portion of the area needing to be managed. Coordinated efforts of adjacent land management units will likely be required to facilitate these shifts. Restructuring of plant communities to “preferred microclimates” may be possible within a management unit and is already being implemented by managers as a hedge against the loss of species. It has been observed that by altering plant communities, the fundamental unit of many conservation plans, these large and small scale changes undermine contemporary conservation.

Under climate change, the scale of the plant communities may not be relevant to the designated new conservation area. Plant communities are often used as surrogates for habitat

availability for one or many species. However, plant community composition and distribution is dynamic as has been demonstrated by paleoclimatic evidence showing individuals, and not communities, responding to climate change over time. These changes to plant communities will also disrupt contemporary efforts to measure ecosystem functional connectivity. Individualistic responses to climate change effects connectivity metrics because functional connectivity is typically inferred from structural connectivity of vegetation cover types. As structure changes with vegetation shifts, the challenge facing managers is to determine if functions change as well. Furthermore, contemporary conservation planning needs to incorporate shifts in populations due to climate change and consider that areas with smaller endemic populations may provide significant genotypes as well as larger genetic pools.

Although climate change is affecting ecosystems today, the uncertainty and the unpredictability of future climate impacts makes it difficult to develop plans and projects to mitigate its impacts at the scale of a contemporary conservation project. Furthermore, a climate-based conservation plan will probably be more expensive to implement than a traditional plan because the climate based plan will require more land area to buffer species against uncertain environmental changes. Despite these uncertainties in global climate models, conservation planning has to consider the future repercussions of climate change because it will likely decrease the future efficacy or eliminate all the benefits derived from contemporary conservation projects.

Future Directions and Emerging Challenges in Conservation

With the widespread and increasing loss of earth’s biological diversity, conservationists face an ever-increasing list of challenges that they need to consider when developing conservation plans. Some of the most urgent and important issues facing contemporary conservationists include: (1) The development of robust place-based conservation strategies, (2) achieving conservation objectives in the face of short election cycles and increasingly crowded political agendas, (3) getting social and economic incentives aligned with conservation, (4) developing institutions to manage for ecosystem resilience and sustainable development, (5) managing for climate change, (6) restoring damaged ecosystems, (7) generating the economic and political capital necessary to achieve conservation objectives, (8) mitigating the impacts and reducing the spread of invasive species, (9) developing a stronger constituency for conservation through media and education campaigns, and (10) strengthening intergovernmental and international institutions for the conservation of biodiversity. These issues vary from the species to global scales even though conservation planners will need to focus on local to regional scales to achieve their goals of increasing conservation efficacy. They will need to understand these larger scale issues since decisions made at these scales will have repercussions on where conservation is possible and what can be practiced at the conservation project scale.

Conservation planners need to make many trade-offs, from what to conserve and where to establish conservation projects,

so conservation goals are realistic to pursue. Trade-off choices need to be made since we recognize that there are few new unexplored lands that can be converted solely to conservation. UNEP World Conservation Monitoring Centre (UNEP-WCMC) reported that 13% of the terrestrial landscape was in protected status in 2010. The competing demands for using the same land suggest that it will be difficult to significantly increase the amount of land set aside for biodiversity protection. Conservation planning has to accept that the land area is finite and must be shared with many other stakeholders.

Today the practice of conservation will need practitioners who are familiar with the knowledge and tools to integrate cultural resources, environments resilience, and economic constraints to address these competing demands. Since no conservation project can satisfy the competing demands of all of the stakeholders, conservation planning is increasingly becoming more sophisticated and now requires expertise of modelers using numerous algorithmic and optimization tools to help reconcile trade-offs among competing alternatives. Therefore, conservation planners must have tools allowing them to explore the repercussions and the trade-offs needed to be made among multiple competing demands and identify the places where resources are finite. Reaching compromise solutions may require considering a multitude of options. Economic evaluation is one of the tools that may facilitate making conservation choices but its use has to be placed in the cultural and environmental context. Today multi-objective modeling tools are being developed to examine the tradeoffs associated with maintaining ecosystem resilience (e.g., biodiversity habitat) and social resilience (e.g., whether a sustainable livelihood is possible). These models also need to factor in the vulnerability of the environments and society to climate change since these will impact conservation efficacy.

Many of the challenges mentioned already are interconnected so that as solutions are developed for one challenge, it will facilitate resolving problems faced by the other challenges. It is imperative that conservation planners are able to overcome these challenges since conservation efficacy hinges on producing the right solutions. Some of the major challenges for conservation efficacy are social. The pressures of human activity and population growth will probably be the major determinants of whether a conservation plan can be designed to successfully conserve a given species. Sometimes the scientific knowledge of how much area is needed by a

species cannot be implemented in the face of these social pressures. In these cases, it is appropriate to use science to determine the necessary size of the conservation reserve, but managers must keep in mind that social and economic variables are exerting more control on whether the reserve will be able to protect its resident biodiversity.

Glossary

Anthropocentric Human-centered in perspective, especially with regard to the value of the natural world.

Biocentric Valuing the existence and diversity of all biological species.

Conservation biology An integrative approach to the protection and management of biological diversity that uses appropriate principles and experiences from the natural sciences, the social sciences, and various resource management fields.

Preservation The school of conservation philosophy that emphasizes the protection of natural features and landscapes from human exploitation.

Progressive Era The period in American political history, especially coinciding with the presidency of Theodore Roosevelt (1901–1909), in which the conservation movement gained definition.

Sustainable In general, capable of meeting economic goals in a manner that does not degrade the quality of the underlying ecosystem.

Sustained yield The management and harvesting of renewable resources in a manner that does not exceed their rate of replacement or reproduction.

Utilitarian The school of conservation philosophy that emphasizes the value of the natural world in contributing to human well-being, especially in terms of economic standard of living.

The Background of Conservation

As a conscious goal of citizen action, public policy, scientific research, and professional endeavor, conservation first gained coherence in the late nineteenth and early twentieth centuries. Over the decades, the conservation movement has evolved in response to varied forces: Emerging findings in the natural sciences, new environmental threats, shifts in philosophical assumptions and esthetic standards, novel technologies, expanding legal mandates, and constantly changing social, economic, and political conditions. The complex interplay of these forces has produced a movement that remains in flux and whose goals continue to evolve, even as the world's ecosystems face increasing challenges to their diversity and integrity.

Prehistoric Precedents

The term conservation acquired its modern meaning in the early twentieth century with the rise of the Progressive Era conservation crusade in the USA. However, as an expression of cultural commitment to an enduring and resilient relationship with the natural world, conservation has much deeper historic and prehistoric roots.

Prehistoric peoples did not live in a simple or constant state of peaceful coexistence with and within their natural surroundings. Converging lines of evidence from paleontology, paleoecology, archeology, and anthropology suggest in fact a sobering picture of the human past: That the dispersal of the human population over the past 120,000 years has been accompanied by spasms of continental and insular extinction (among other forms of environmental degradation). The best known of these prehistoric extinction events involves the disappearance of mastodons, ground sloths, camels, giant beaver, and other large North American mammal species coincident

with a major wave of human colonization between 12,500 and 10,000 years ago. The same general pattern of extinction has been traced back over the centuries as humans moved out of Africa and Eurasia into Australia, Polynesia, and island groups around the world. The implications of this pattern of “dreadful synecopation” are controversial, and research continues on the exact sequence of cause and effect, the interaction of probable causal factors, and the precise mechanisms of extinction (MacPhee, 1999).

However, in contrast to this record of prehistoric anthropogenic extinction, there is the countervailing experience of many cultures that have achieved relatively sustainable ways of life. Native peoples in landscapes throughout the world developed sophisticated belief systems and resource-use traditions that recognized their connections to and dependence on the nonhuman world. In the past, these traditions allowed people to adapt to even extreme environments throughout the world. For example, the Maasai of East Africa, practiced live-stock herding in a manner that allowed them to coexist with the native megafauna of their semiarid homeland. Arctic dwellers coexisting with caribou herds and marine mammals, shifting cultivators and agroforesters in the humid tropics, small-scale farmers in temperate zones, fishing villages in coastal, riverine, and wetland environments: These and other traditional cultures developed social systems that balanced human needs against the capacity of the natural environment to meet those needs. Some of these traditions have survived into the modern era, though they must contend with increasing pressures from population growth, diminished resources, altered land tenure systems, climate change, and rapid economic and technological change.

The resource-use practices of native peoples had significant impacts on the biota, though these impacts varied in intensity over time and according to ecosystem type and taxonomic group. People employed fire to modify vegetation and to concentrate populations of game animals. They fished,

hunted, and gathered in ways that affected species populations, animal behavior, and the dynamics of interspecific relationships. They domesticated plant and animal species, and altered natural hydrological systems through irrigation. In some cases – for example, the deforestation of Mediterranean watersheds and the development of hydraulic cultures in arid and semiarid lands – large-scale resource exploitation caused fundamental changes in biological diversity and ecosystem function. In other cases, the limited rate and scale of exploitation resulted in relatively minor long-term ecological impact.

Humanized landscapes, in sum, have experienced varying degrees of anthropogenic environmental change (Ellis, 2011). However, in many if not most native cultures, social mechanisms evolved to reinforce an attitude of respect and deference toward nature, to evoke nature's bounty, and to sanction appropriate human use of that bounty. These mechanisms included hunting, planting, and herding rituals; stories and myths involving social and ecological relationships; fertility and birth control practices; the recognition of sacred spaces; and the invocation of taboos and totems. The conservation movement might be characterized as modern society's conscious effort to develop and exercise analogous social practices and restraints to guide its relations with the nonhuman world.

Historic Precedents

Contemporary environmental dilemmas have prompted modern scholars to reexamine conservation traditions in texts and stories from animist, Native American, Buddhist, Hindu, Islamic, Judeo-Christian, and other faith traditions (Taylor, 2005). For example, in the Judeo-Christian tradition, the biblical injunction to “fill the earth and subdue it, and have dominion over every living thing that moves on the earth” has often been cited as providing justification and rationale for centuries of environmental exploitation in the Western experience. More recently, scholars have returned to such textual sources to identify alternative traditions of stewardship and respect for creation.

Since ancient times, observers have recorded instances of environmental deterioration due to human action. For example, Plato compared the deforested mountains of Attica to the “bones of a wasted body ... the richer and softer parts of the soil having fallen away, and the mere skeleton being left” (Dubos, 1980). Evidence of early conservation practices can be found in the history of both Western and non-Western cultures. These include efforts to protect particular species and special lands, to maintain populations of wild plants and animals, and to sustain the productivity of agroecosystems. For example, Leopold (1933) cited Marco Polo's narrative account of hunting restrictions and provisions for game bird populations in thirteenth-century China as “the first clear record of a well-rounded system” of wildlife conservation.

European traditions of forestry and game-keeping date back to the Middle Ages and beyond. The establishment of royal game preserves and forests on the land estates of feudal Europe led to the development of customs and formalized laws regulating hunting and use of the forests. In the eleventh century, William the Conqueror set up in the newly conquered England “many deer preserves and also enacted laws/That

whoever killed a hart or hind/Should be blinded./He also placed a ban on harts, also on boars” (Harrison, 1992). The high-handedness of the Norman conquerors in establishing privileged use of the forests gave rise to a venerable tradition of local resentment over centralized resource management. However, as codified in forest law, these measures allowed England's forests to survive and regenerate. On the continent, Germany and France, in particular, developed silvicultural systems and techniques that prevented wholesale destruction of the forest estate.

Europeans carried these “proto-conservation” traditions to their expanding colonial empires. The change in jurisdiction over natural resources, from native peoples to colonial and state governments, had profound implications for social systems and ecosystems alike (Cronon, 2003). Colonial domination, coupled with rising populations and industrialization, disrupted traditional patterns of land tenure and resource use. In many regions, native peoples became increasingly alienated from their landscapes, whereas Western conservation ideas and practices were slow to adapt to the new environments.

In the New World, European colonists encountered a landscape of abundance that admitted profligate resource use. Unchecked resource exploitation was the norm as European settlement of North America proceeded. Despite this record, seeds of the later conservation movement were apparent in early efforts to protect wild game populations, forests, soils, and special natural features. Early measures to conserve game include decrees to protect the cahow (*Pterodroma cahow*) and green turtle (*Chelonia mydas*) in Bermuda (1616–1622); the first closed hunting season on white-tailed deer (*Odocoileus virginianus*) in Massachusetts (1694); closed seasons on several species of game birds in New York (1708); and the institution of game warden systems in Massachusetts (1739) and New York (1741) (Matthiessen, 1959). The first federal game law, enacted in 1776, mandated closed seasons on deer in all the American colonies except Georgia. Through the 1800s, the new American states intermittently passed laws establishing closed seasons, prohibiting hunting of nongame birds, and placing bounties on predators.

Exploitation of North America's extensive native forests – for conversion of land to agriculture, for construction and ship-building materials, for charcoal and domestic fuel supplies – drove economic development through much of the colonial and early American era. In the late seventeenth and early eighteenth centuries, the British crown instituted the Broad Arrow policy, which reserved for the crown the right to cut the strategically important white pine (*Pinus strobus*) mast trees of the New England colonies. Although serving to restrict exploitation, these laws were intended more to secure property against unauthorized timber cutting than to protect or perpetuate the forests *per se*. Closer in intent to later forest conservation measures was William Penn's 1681 dictum that, in the process of land development, one acre of forest should be maintained for every five acres cleared.

Little heed was paid to such recommendations. By 1745, Benjamin Franklin was noting the scarcity and high cost of fuelwood in Philadelphia. President James Madison in 1818 drew attention to the “injurious and excessive destruction of timber and firewood” as the most important and regrettable force shaping the rural economy of the USA. Such

destruction continued through the nineteenth century. With the depletion of the eastern forests and the continuing settlement of interior North America, the focus of forest exploitation shifted to the Great Lakes region. In 1831, Alexis de Toqueville, while visiting Michigan, noted that Americans were generally “insensible to the wonders of inanimate nature, and may be said not to perceive the mighty forests that surround them till they fall beneath the hatchet.” The swift destruction of the Great Lakes forests in fact marked a turning point in forest conservation, and in the conservation movement generally (Williams, 1989).

A parallel pattern of resource degradation and early conservation response marked the process of agricultural development in North America. By 1776, the problem of soil erosion was evident to the new nation’s leading statesmen. Thomas Jefferson experimented with contour plowing to retard soil erosion. Patrick Henry, speaking before the Virginia Assembly, stated that “Since the achievement of our independence, he is the greatest patriot who stops the most gullies.” George Washington noted in a 1797 letter, “We ruin the lands that are already cleared and either cut down more wood if we have it, or emigrate into the western country” (Jackson, 1985). Over the next century, destructive agricultural techniques continued to affect widely varied ecosystems across North America (and other parts of the world as well).

The preservation impulse in conservation found special expression in the North American setting, as European settlers encountered scenic landscapes and natural features unlike any in their prior experience. Jefferson celebrated Virginia’s Natural Bridge in his Notes on the State of Virginia. Niagara Falls, the Hudson River valley, and the prairies, mountains, and canyons of the American West became emblematic of the esthetic quality of New World landscapes, a quality seized on by artists, promoters, and early conservationists alike. The artist George Catlin suggested after his first excursions in the West that portions of the continent’s undeveloped lands were “worthy of our preservation and protection.” As early as 1833, Catlin envisioned government reservation of “a magnificent park ... a Nation’s park, containing man and beast, in all the wild[ness] and freshness of their nature’s beauty” (Nash, 1982). Such protected areas would not come into being until later in the nineteenth century, although the USA did move as early as 1832 to protect special natural features when it reserved Hot Springs in Arkansas as a federal holding.

What these disparate efforts had in common was not the conservation of biological diversity in the modern sense, but the protection or regulated exploitation of economically and esthetically important components of the landscape or ecosystem. As such, they provided the foundation on which a more coherent conservation movement began to take shape in the latter half of the nineteenth century.

Modern Origins of Conservation

Prelude to a Movement

The conservation movement emerged in response to accelerated changes in demographic and environmental conditions, and in human perceptions and understanding of the natural

world, through the eighteenth and nineteenth centuries. Exploration of the world’s diverse ecosystems – from the earliest voyages of discovery through the New World scientific expeditions of Alexander von Humboldt, John and William Bartram, Meriwether Lewis and George Rogers Clark, John James Audubon, and others – contributed to a golden age of natural history studies. Establishment and adoption of the Linnean system of binomial nomenclature in the 1700s allowed for an unprecedented flourishing of taxonomic research (Mayr, 1982). This, in turn, provided critical foundations for the development of evolutionary theory in the work of Alfred Russel Wallace and Charles Darwin. Although the biological sciences had not yet developed field methods for comprehending the full diversity of life, they had begun to reveal the fundamental processes through which life diversified and maintained itself.

These gains in systematics, biogeography, and evolutionary theory occurred even as the Industrial Revolution and the expansion of market economies accelerated the scale, pace, and character of human environmental impacts. Through the 1800s, the advent of more efficient technologies resulted in increasingly intensive exploitation of forests, game populations, fisheries, agricultural lands, and river systems. Traditional resource management practices and established land tenure systems were abandoned or changed to fit the emerging economies of scale. Industrial pollution and the global spread of invasive species became widespread problems for the first time.

Coincident with these scientific, cultural, and environmental changes, the Enlightenment and Romantic movements were altering Western conceptions of order, value, and beauty in the natural world. The natural philosophers of the Enlightenment stressed the smooth workings and stability of a mechanistic natural order. The Romantic philosophers and poets emphasized the unity and wholeness to be found in a spontaneously creative organic nature. Although offering different conceptions of nature, both encouraged human comprehension of natural objects and processes, and so laid the foundation for greater appreciation of human impacts on the natural world. The writings of Thomas Malthus and other early economic philosophers provided the basic framework for considering the interwoven fate of the human population, human economies, and natural resources.

In Europe, the Romantic Movement drew heavily on the experiences of New World explorers and settlers, the encounter with native peoples there and elsewhere, and the exposure to wild landscapes. In turn, adaptation of the Romantic impulse in the North American setting provided important literary and philosophical foundations for conservation. For example, the strong American identification with wild nature found early expression in the essays of the transcendentalists Ralph Waldo Emerson and Henry David Thoreau, the poems of William Cullen Bryant, and the novels of James Fenimore Cooper (Nash, 1982).

George Perkins Marsh’s *Man and Nature: Or Physical Geography as Modified by Human Action* (1864) is widely considered the first great landmark in modern conservation literature. A native Vermonter, Marsh saw in the destruction of New England’s forests, the latest expression of an ancient human tendency to “[derange] the original proportions between

different orders of organic life." Drawing also on his extensive personal observations of long-term landscape change in New England and the Mediterranean, Marsh argued that the human actions had caused widespread disruption of the "harmonies" of the natural world. Marsh's reasoning followed lines that would sound familiar to later generations of ecologists and biodiversity conservationists. "All nature," he wrote, "is linked together by invisible bonds, and every organic creature, however low, however feeble, however dependent, is necessary to the well-being of some other among the myriad forms of life with which the Creator has peopled the earth" (Marsh [1864], 1965).

Gaining Definition

Publication of Marsh's book provided direction and definition to the nascent conservation movement through the remainder of the 1800s and the first decade of the 1900s. In North America, dispossession of the Native American tribes, enactment of liberal land distribution policies, and the flow of settlers and capital into "virgin" landscapes resulted in an unprecedented wave of exploitation of natural resources. The effects were visible in ecosystems across the continent. These decades saw the virtual depletion of the extensive pine forests of the upper Great Lakes; overhunting of many game bird and mammal species by market hunters; rapid conversion of the Midwest's extensive prairies to agriculture; degradation of aquatic systems through overfishing, pollution, and hydrological changes; and widespread overgrazing of the semiarid western rangelands. Several well-recognized cases of species depletion and extinction – of the white pine, of waterfowl, of the bison (*Bison bison*), the Carolina parakeet (*Conuropsis carolinensis*), and the passenger pigeon (*Ectopistes migratorius*) – came to symbolize this era of unmitigated resource extraction and decline (Barrow, 2009).

However, this period also saw the first concerted efforts to address the causes and consequences of these massive changes. At first, these actions tended to focus on particular issues, species, problems, or landscapes. Sportsmen led the campaign to rein in market hunting and to institute stronger game laws at the state and local levels. Many of the nation's most prominent sportsmen banded together in 1887 to form the Boone and Crockett Club, one of the first and most effective nongovernmental organizations to become involved in shaping national conservation policy. Exploitation of plume-bearing egrets and other birds for the millinery trade mobilized sportsmen, scientists, and nature lovers to work together for reform, and prompted formation of state Audubon Societies beginning in 1896. These moves culminated in passage of the federal Lacey Act of 1900. The first important piece of modern wildlife conservation legislation, it barred interstate shipment of wild animal species taken in violation of state laws, and soon succeeded in ending the plume trade (Dunlap, 1988).

Efforts to reform American land policy proved more difficult. Through the 1800s, the nation's land allotment policies had encouraged rapid immigration, settlement, and land conversion, often accompanied by corruption and land speculation. In the midcontinent's mesic landscapes, the

system of land surveying and distribution facilitated the conversion of millions of acres of native savanna and grassland to crop and livestock production. However, these policies were less tenable in the progressively drier lands of the American West, where farming was possible only near permanent watercourses, and livestock ranching required large land holdings. The geologist and explorer John Wesley Powell attempted in the 1870s and 1880s to devise a more appropriate tenure system that recognized the inherent environmental limitations and social requirements of the landscape, but the speculative momentum proved intractable. Only decades later did the US government institute more careful land management policies on the nation's remaining public domain. However, Powell's innovations, especially his commitment to a strong role for science in land management, laid important foundations for future private and public conservation planning (Worster, 2001).

The rapid destruction of forests in the upper Great Lakes between 1865 and 1900 stimulated the most forceful and effective response among early American conservation reformers. As this period began, forestry as a profession had not yet gained a foothold in the USA. However, through the 1870s and 1880s, voices opposed to the destructive "cut and run" logging practices began to emerge. These reformers included botanists Charles S. Sargent, Asa Gray, and William H. Brewer; naturalists John Muir and Increase Lapham; the European-trained forester Bernard Fernow; Secretary of Interior Carl Schurz; and Franklin B. Hough, appointed as the nation's first government forestry official in 1876.

The forestry movement gained momentum quickly in the last decade of the nineteenth century. Forest activists working through professional scientific and forestry organizations campaigned for national legislation to reform public land laws and prevent further forest destruction. These efforts culminated in 1891 with the enactment of legislation that included a provision allowing the US president to set aside public land forests as forest reserves, the germ of the nation's current system of national forests. Within weeks of its passage, President Benjamin Harrison used the law to designate forest reserves in lands adjacent to Yellowstone National Park. In the next 10 years, 47 million acres of forest land were placed in reserves.

During this period a parallel movement arose to protect and preserve special scenic landscapes, natural features, and wild spaces. Like the forestry movement, this channel of activism gained momentum in the decades following the American Civil War. In 1872, the US Congress established the world's first national park at Yellowstone. In 1885, New York created a state forest preserve in the Adirondack Mountains in order to protect its wild character as well as its watershed values. That same year, Canada designated Banff National Park, its first. The impetus toward preservation drew heavily on the enthusiasm of nature writers such as John Muir, who led the political effort that in 1890 resulted in designation of an enlarged Yosemite National Park in California and who in 1892 founded the Sierra Club (Fox, 1981).

At the end of the nineteenth century, the varied strands of conservation concern – over depleted wildlife, widespread deforestation and watershed degradation, inappropriate land development, industrial pollution, and the loss of esthetic

quality – were connected only loosely. In the American experience, political corruption and inordinately concentrated wealth had typically accompanied these environmental changes. As the new century began, these overlapping social, economic, political, and environmental concerns brought forth a more consolidated movement that gave new meaning and power to the term *conservation*. However, the growing prominence of conservation also revealed inherent tensions in the emerging movement.

Progressive Era Conservation and the Utilitarian/Preservationist Split

When Theodore Roosevelt assumed the American presidency in 1901, the stage was set for a revolution in conservation policy. Roosevelt brought to the office a formidable command of the natural sciences, extensive experience as a rancher and outdoorsman in the American West, a long-standing commitment to political reform, and boundless personal energy. In his first presidential address to the US Congress, Roosevelt spoke at length of the importance of the nation's forests, stating that "We have come to see clearly that whatever destroys the forest ... threatens our well-being" (Pinchot, 1947). Conservation became a cornerstone of the progressive political movement and, for the first time in history, a high national priority.

Roosevelt's partner in political innovation was forester Gifford Pinchot (Miller, 2001). Pinchot, the first American to receive formal training in forestry, was a friend of Roosevelt's who had been active in the complex politics of the American forestry movement through the 1890s. At the time Roosevelt became president, Pinchot was in charge of the Division of Forestry in the US Department of Agriculture. The two quickly forged a close alliance to strengthen the government's role in forestry. Their partnership during Roosevelt's presidency resulted in an increase in the total acreage of the forest reserves (renamed national forests in 1905) from 60 million to 151 million acres; transfer of these lands to the Department of Agriculture under Pinchot's jurisdiction; and the creation, in 1905, of the US Forest Service to administer the new national forests.

Pinchot's Forest Service embodied the Progressive Era spirit and its approach to bureaucratic responsibilities. In contrast to Muir and others in the preservationist wing of the conservation movement, Pinchot conceived of the forest in utilitarian terms. The forests were not regarded as "reserves" to be "locked up," but as lands to be worked "for the greatest good of the greatest number for the longest time" (as the utilitarian credo put it). In practice, this meant that the forests were to be managed by a trained, professional workforce; that scientific principles were to guide the efficient exploitation and processing of forest resources; and that the wealth derived from the forests was to be equitably distributed for the common good (Hays, 1959). Applied not only to forests but also to natural resources in general, the "resource conservation ethic" provided the dominant paradigm of the early movement (Callicott, 1991). In Pinchot's words, "The first great fact of conservation is that it stands for development" (Pinchot [1910], 1967).

At the core of utilitarian conservation was the concept of sustained yield. As Aldo Leopold later (1933) observed, under the progressive conservation banner "wild life, forests, ranges, and waterpower were conceived ... to be renewable organic resources, which might last forever if they were harvested scientifically, and not faster than they reproduced. "Conservation" had until then been a lowly word, sleeping obscurely in the dictionary. The public never heard of it. It carried no connotation of woods or waters. Overnight it became the label of a national issue". At the leading edge of this movement, the Forest Service became a model not only for other resource management agencies but for Progressive Era government agencies in general.

Theodore Roosevelt's conservation activism extended beyond the public forests. During his presidency, he established the nation's first wildlife refuge, at Florida's Pelican Island (1903); designated 50 additional wildlife refuges; used new presidential powers under the Antiquities Act of 1906 to set aside 18 national monuments (including the Grand Canyon); convened in 1908 a national Governors' Conference on the Conservation of Natural Resources; and created, also in 1908, a National Conservation Commission to provide continuing advice to the president and to work with the states on conservation policy. Early in 1909, Roosevelt and Pinchot sought to broaden the scope of conservation through a North American Conservation Conference and laid still more ambitious plans for a World Conservation Conference. Though the latter was unrealized, Pinchot and Roosevelt had succeeded in securing a place for conservation within both the political and actual landscape.

Absent from many of the progressive political initiatives were the voices of the increasingly influential preservationists and nature protectors. In contrast to the utilitarian view that Pinchot espoused, adherents of the "romantic-transcendental preservation ethic" emphasized wild nature's esthetic and spiritual values and the need to safeguard those values for future generations through strict prohibitions on development and manipulation (Callicott, 1991). The tensions between the utilitarian and preservationist approaches intensified as conservation assumed center stage politically. These tensions surfaced in the changing relationships among the principal players. Pinchot and John Muir had been friends, but by the late 1890s, their differing approaches to management of the forest reserves caused a rift between them that would never heal. Few from the preservation camp participated in the landmark 1908 governors' conference on conservation.

Muir maintained a respectful relationship with Roosevelt. They camped together in Yosemite in 1903 and worked together in gaining protection for the Grand Canyon as a national monument in 1906. But the schism between the conservation factions continued to widen. It came to a head in the bitter political struggle over plans to dam the Tuolumne River in Yosemite National Park's Hetch Hetchy Valley. Waged over a period of 6 years, the battle culminated in 1913 with the adoption of national legislation providing federal support for the dam. Although Muir and his colleagues lost the battle, they had aroused a national constituency in favor of protection. The growing popular and political acceptance of preservation led directly to creation of the US National Park Service in 1916 (Fox, 1981).

For all of the profound developments in conservation during the Progressive Era, scant attention was given to the state of the ecological processes and biological diversity characteristic of either wild or more humanized landscapes. That attention would come only slowly, as conservation science, philosophy, policy, and practice coevolved through the twentieth century.

The Evolution of Twentieth-Century Conservation

The Progressive Era advances fixed conservation permanently in the public mind and in public policy. However, the innovations of the period served only to highlight the fundamental questions that would challenge conservationists throughout the twentieth century: What are we conserving? To what end? For whom? How? With what scientific information and understanding? With what social adjustments, economic mechanisms, and legal tools? Moreover, the conservation movement emerged from the Progressive Era with the tension between preservationist and utilitarian approaches still unresolved. The continuing efforts to answer those questions and to resolve that tension framed the century's technical and political advances in conservation.

Institutionalizing Conservation

In the USA, the first four decades of the twentieth century saw the consolidation of the Progressive Era's conservation gains in the government, the private sector, the professions, and the academy. The spirit of reform that drove the conservation movement was now redirected toward the development of sound conservation policy and administration. However, new issues arose to keep the movement invigorated and expand its philosophical dimensions.

As conservation became institutionalized, it tended to follow the tenets of Pinchot's resource conservation ethic. By the late 1930s, the basic principles of utilitarian resource conservation had been applied not only to forests but also to other "useful" components of the biota and the landscape: rangelands, game populations, sport and commercial fisheries, scenic lands and recreational areas, agricultural soils, and river systems. New policies, laws, bureaucracies, academic disciplines, research and training programs, and professional societies arose to promote sustained yields of these various "resources." Foresters, range managers, wildlife managers, recreation planners, and soil conservationists achieved their own professional identities in these years. Amateur conservationists, meanwhile, became increasingly involved in decision making through the formation of new citizen organizations.

Forestry

As an established field, forestry provided the model and foundation for the other emerging resource management professions in the USA. With those fields still lacking formal training and employment opportunities, forestry tended to attract professionals with broad conservation interests. However, institutionalization tended over time to narrow the scope

of the field to silviculture and timber harvesting. This trend was magnified during these decades as the supply of timber taken from private lands diminished and the pressures on public forests increased.

Range Management

In the American West, rapid settlement and exploitation had degraded vast stretches of arid and semiarid grassland in the late 1800s and early 1900s. Research and academic training programs followed in the wake of deteriorating range conditions, bringing scientific management to rangelands much as forestry had brought such management to forests. By the late 1930s, changes in land policy resulted in stricter regulation of the public rangelands, cessation of privatization of the public domain, establishment of a new federal bureau (the Bureau of Land Management) to oversee these lands, and the emergence of range management as a discrete field.

Wildlife Management

Although concern about the fate of game populations had often galvanized the young conservation movement, wildlife management did not carve out its own professional niche until the 1930s. Continuing declines in game populations provided the initial impetus. To arrest these declines, game protectors at first focused on enactment of stricter hunting regulations, sporadic establishment of refuges, development of artificial propagation programs, control of predators, and the introduction of exotic game species. Only in the early 1930s did a revolutionary new approach, focused on the protection and restoration of habitats so that populations might sustain themselves, begin to take hold. (Fisheries management followed a roughly parallel pattern with regard to game fish species and habitats.) As principles from ecology filtered into the field, the term *wildlife* itself came into common usage, and the idea of management quickly expanded to encompass the perpetuation of "nongame," rare, and threatened species. Although the field tended to focus primarily on game species, it provided important foundations for efforts later in the century to conserve biological diversity in general.

Recreation

As the American population became increasingly urban and mobile, outdoor recreation became a more important component of conservation. Camping, fishing, hunting, hiking, and other outdoor activities continued to grow in popularity, even after the prosperity of the 1920s gave way to the Great Depression of the 1930s. Park agencies, at all levels of government, responded by establishing and developing areas of significant esthetic and recreational value. Other land management agencies, such as the US Forest Service, began to devote greater attention to the recreational value of the lands under their jurisdiction. Although there were exceptions, recreational developers tended to override or ignore problems associated with the protection or management of the biota, and rarely incorporated scientific information in planning for increased tourism.

Soil Conservation

The rapid expansion and mechanization of agriculture in the early decades of the twentieth century brought widespread

disruption to the agricultural landscape and economy. The disaster of the Dust Bowl in the Southern Great Plains during the mid-1930s was the most visible consequence of forces that had degraded soils across North America. Intensified exploitation of farm resources through land clearing, “clean farming,” poor grazing management, and wetland drainage led to accelerated rates of soil erosion, degradation of pasture and forage vegetation, loss of wildlife habitat, and aggravated cycles of siltation and flooding. In response, the US Congress in 1935 created the Soil Conservation Service (SCS) to work with farmers and other private landowners to adopt conservation practices. Under the leadership of Hugh Hammond Bennett, the SCS importantly emphasized watershed-scale approaches that integrated soil protection measures with other resource conservation goals (Egan, 2006).

Although increasingly defined by this enhanced structure of agencies, disciplines, and professions, the conservation movement remained a battleground for competing approaches and intense political activity. Even as conservation became professionalized, growing numbers of citizens became active as members of nongovernmental conservation organizations. New national groups, including the Izaak Walton League, the National Wildlife Federation, and Ducks Unlimited, joined such older organizations as the Sierra Club and the Audubon Association as significant players in shaping conservation policy (Fox, 1981).

Meanwhile, the preservationist approach found renewed vigor as the campaign to protect wildlife, natural areas, and wildlands reemerged in the 1920s and 1930s. In these years, field zoologists such as Joseph Grinnell and Olaus Murie became leaders in the effort to reverse government antipredator policies. Early ecologists, under the leadership of Victor Shelford, created in 1917 a Committee on the Preservation of Natural Conditions within the Ecological Society of America. This committee provided the nucleus for what became, decades later (1950), The Nature Conservancy. In 1924, the US Forest Service designated the nation’s first “wilderness area” on a large roadless expanse of the Gila National Forest in New Mexico. In 1935, proponents of wilderness protection in the USA banded together as The Wilderness Society, the first conservation organization dedicated solely to the cause of wildland protection. Although the wilderness protection movement still emphasized primarily the esthetic, spiritual, and recreational value of wildlands, these moves signaled a shift toward greater recognition of the scientific and ecological value of undeveloped lands.

At the international level, the years prior to World War II saw increased recognition of the global scope of conservation challenges and halting moves to institutionalize a response to those challenges. The Western powers – particularly the USA, Britain, France, and Germany – continued to export forestry and national park programs to their colonies and protectorates. Early international conventions and treaties addressed the problems of protecting fur seals, sea otters, whales and other marine species, and migratory birds (Matthiessen, 1959). In 1913, an International Conference on the Protection of Nature in Switzerland attracted representatives from 16 nations. World War I prevented this effort from gathering momentum, but in the 1920s and 1930s intermittent steps were taken toward greater international cooperation: a second

international conservation conference in Paris in 1923; establishment in 1928 of an International Office for the Protection of Nature in Brussels; an unprecedented international bird conservation conference in Paris in 1933; a Conference for the Protection of African Fauna and Flora in London, also in 1933; the first North American Wildlife Conference in 1936; establishment of the Pan-American Union, dedicated largely to conservation issues in the Western Hemisphere, in 1940 (Nash, 1982). These set the stage for the expanded international programs that emerged in the aftermath of World War II.

Conservation Amid Crisis: The 1930s and 1940s

The social and environmental convulsions of the 1930s and 1940s fundamentally altered perspectives and priorities within the conservation movement. The Depression forced conservationists and nonconservationists alike to consider the connections between human economic systems and the sources of wealth in nature. In practical terms, the New Deal programs in the USA vastly increased governmental support for conservation programs, though often with little consideration of ultimate conservation goals. The experience of the Dust Bowl focused the attention of conservationists and many natural scientists on the consequences of indiscriminate exploitation of sensitive lands, highlighting especially the systemic nature of the soil erosion problem. With the outbreak of World War II, conservation issues fell into the background of concerns, proving the difficulty of maintaining mindfulness of human–nature relationships when social crises erupt. As in no time since the Progressive Era, these years of crisis demonstrated the interwoven nature of social, economic, and environmental problems.

As a movement, conservation remained prominent in North America and elsewhere, with growing popular and political acceptance. But for all of the recent advances, the conservation movement still suffered from its own internal crisis. Beneath the very active surface of conservation, there remained the underlying philosophical rift between the utilitarian and preservationist approaches. Neither approach adequately addressed such extensive problems as soil erosion and exhaustion, disruption of hydrological cycles, endangerment and loss of wildlife species, and the degradation of biotic communities (both terrestrial and aquatic). For a small but growing group of conservationists, the Dust Bowl (among other factors) stimulated a new effort to address the roots of conservation problems, one that would draw on elements of both the utilitarian and preservationist schools. Embracing the preservationist critique of human hubris in manipulating the natural world, the esthetic appreciation of wild nature, the traditional commitment to wise use and stewardship of resources, and the value of science in the service of conservation, this cohort of conservationists sought to define a more robust synthesis to guide conservation action.

The incipient synthesis reflected a basic shift in conservation’s scientific foundations. Theory and application – that is, the science and practice of conservation – were meeting in ways they had not before. Developments in ecology and evolutionary biology over the previous decades had begun to inform

conservation issues, even as contemporary problems forced conservationists to reexamine their scientific assumptions. Ecology was revolutionizing scientific understanding of the functioning of biological communities, landscapes, and systems. Evolutionary biology provided new perspectives on, for example, the adaptations, roles, and interactions of all forest species (in contrast to the basic descriptive botany, dendrology, timber physics, and forest mensuration on which silviculture and forestry had previously rested).

For at least some conservationists, these scientific advances suggested a new need: to marry ecology and the various fields of resource management in the effort to sustain, not just the yields of particular commodities, but the healthy functioning of the systems generally. The preeminent voice of this emerging approach was the American forester and wildlife ecologist Aldo Leopold, who in the course of his career had applied ecological principles first to the conservation of forests, then to soils, watersheds, game and wildlife species, then ultimately to the land “as a whole.” Writing in 1939, Leopold noted that ecology provided “a new fusion point for all the natural sciences” and that its emergence had placed the economic biologist in a peculiar dilemma: With one hand, he points out the accumulated findings of his search for utility, or lack of utility, in this or that species; with the other, he lifts the veil from a biota so complex, so conditioned by interwoven cooperations and competitions, that no man can say where utility begins or ends. ... The only sure conclusion is that the biota as a whole is useful, and [the] biota includes not only plants and animals but also soils and waters as well (Leopold, 1939, p. 727).

Leopold’s expanded conservation philosophy, as finally expressed in his landmark essay “The Land Ethic” in *A Sand County Almanac* (1949), placed greater emphasis on the ecological integrity, resilience and beauty of what he called “the biotic community” and rejected the view of nature as merely a collection of disaggregated natural resources. It shifted the role of human beings “from conqueror of the land community to plain member and citizen of it” (Leopold, 1949). This proposed shift, away from an anthropocentric and toward a more biocentric approach to the human role in nature, suggested the need for fundamental changes within the various fields of resource management. Resource managers could no longer regard timber trees, game animals, water, soils, scenic vistas, or any other economically or esthetically significant resource as separate entities. Rather, resources had to be seen as components within diverse systems, connected to and interacting in complex ways with other parts of the system (including human beings). It followed that the conservation professions had to develop more integrated approaches to resource management.

As an attempt to address conservation’s underlying schism, Leopold’s “evolutionary-ecological land ethic” would confront continuing challenges in the dramatically altered postwar environment (Callicott, 1991). However, it would also provide those in the conservation movement with new conceptual tools with which to meet those challenges.

From Conservation to Environmentalism

The conservation movement emerged from World War II into a changed world. The war altered conservation’s social and

ecological context. In the world at large, the bonds of empire dissolved in the postwar decades as colonial nations gained their independence. The former colonial powers remained involved in the fate of their erstwhile colonies as donors and providers of development assistance. This in turn altered the shape of the global conservation movement, as aid providers, international agencies, and nongovernmental agencies initiated the long struggle to somehow reconcile international development and conservation priorities.

These changes in international relations occurred even as human population growth, land degradation, air and water pollution, and overexploitation of marine resources first emerged as global-scale conservation issues. The war had demonstrated the interrelated and global nature of modern conservation problems. Fairfield Osborn’s *Our Plundered Planet* (1948) and William Vogt’s *The Road to Survival* (1948) were among the first books to address in an integrated manner issues of global conservation and development. Reflecting this broader scale of concern, a wide spectrum of national and international governments and organizations met in 1948 and formed the International Union for the Protection of Nature with the ambitious goal of preserving “the entire world biotic environment.” Shortly thereafter, the newly established United Nations became involved in international conservation programs.

In the USA, the war years constituted a demographic divide, with important implications for the conservation movement. As veterans and their families resumed their lives at home, the postwar population boom fueled an economic boom that placed increasing demands on natural resources. To meet those demands, war-spawned technologies and industrial processes were quickly adapted for use in the peacetime economy. Over the next several decades, rings of suburbs expanded away from cities into rural lands and, along with dams, highways, and other infrastructural developments, continually reconfigured the landscape.

The postwar years brought a new generation of professionals into agriculture, forestry, wildlife management, and the other conservation fields. Conservation was not immune to the larger social and economic forces in the postwar environment. As the pressure to meet rising demands increased, the resource management professions became more specialized, more focused on commodity outputs, and more inclined to adopt narrow technical solutions to conservation problems. Importantly, the war also changed the ways in which scientific research was supported and conducted, reinforcing the tendency toward specialization and utilitarian applications. The traditional foundations of conservation in systematics, organismal biology, population biology, ethology, and other field-oriented sciences suffered from relative neglect. Collectively, these changes overwhelmed the integrated approach that had begun to emerge prior to the war, requiring conservationists to confront complex environmental problems within an increasingly rigid framework of disciplines and institutions.

However, the postwar years also gave rise to forces that countered these trends. New tools in the earth sciences provided greater scientific understanding of the interrelations within and among terrestrial, aquatic, marine, and atmospheric systems. In the 1950s and 1960s, revolutions in fields ranging from genetics and evolutionary biology to atmospheric

chemistry and geology began to rapidly reshape our understanding of the global biosphere and the human place within it. New communications technologies allowed such information to be shared more efficiently. Meanwhile, the indiscriminate adoption of other technologies – especially in the production of agricultural pesticides, industrial chemicals, and nuclear power – created new concerns over their impacts on human health and ecological systems. With the publication in 1962 of Rachel Carson's landmark book *Silent Spring*, examining the biological impacts of DDT (dichlorodiphenyltrichloroethane) and other pesticides, the modern environmental movement began to assume an identity of its own, distinct from but still connected to the older conservation tradition.

Efforts to protect wildlands in the USA also intensified in the years following World War II. As pressures from urban and suburban expansion, resource extraction, water development, and motorized tourism increased, wilderness protection became a unifying goal among diverse conservation organizations. In 1955, a proposal to build the Echo Park Dam in Dinosaur National Monument in Colorado was defeated, indicating that the conservation movement had gained not only in cohesion but also in popular and political power. That unity led to the passage of the Wilderness Act in 1964, providing for a strengthened national system of wilderness areas on the public lands of the USA.

The Wilderness Act was only one of the many laws adopted during this period of environmental awakening (much as earlier laws had institutionalized the conservation movement). Over the next decade, the US Congress would enact a series of important environmental statutes, including the National Environmental Policy Act (1970), the Clean Air Act (1970), the Clean Water Act (1972), and the Endangered Species Act (1973). These far-reaching changes in environmental policy reflected a rising wave of popular support and organized political activism, symbolized by the observance of the first Earth Day on 22 April 1970.

The Reintegration of Conservation

With the rise of the modern environmental movement, the context of conservation once again changed dramatically. The years following Earth Day saw increasing acceptance, within the conservation professions and within society at large, of environmental values. However, those values were not easily translated into effective conservation action. The resource management professions, in seeking to address broader environmental concerns, found the tendency toward overspecialization difficult to overcome. Conservation programs tended still to focus on single species, or particular economic resources, or separate jurisdictions within a given landscape. As the long-term ecological impacts of such fragmented approaches to resource management became clear, the traditional conservation fields came under increasing public scrutiny. Although many environmentalists pressed for change through legal means, the evolution of management philosophy, policy, and practice would require years of incremental change and adjustment.

At the international level, differences in perspective between the wealthier, developed countries of the North and the

poorer, developing countries of the South likewise proved difficult to overcome. International conservation continued to make important gains through a series of conventions and treaties, including the Convention on Wetlands of International Importance (the "Ramsar Convention") (1971), the Convention on International Trade in Endangered Species (1975), the International Convention for the Conservation of Migratory Species of Wild Animals (the "Bonn Convention") (1978), the United Nations Convention on the Law of the Sea (1982), and the United Nations Convention on Biological Diversity (1992). Again, however, international development policies would incorporate stronger conservation and environmental provisions only gradually, as the need to connect economic development and long-term environmental security became increasingly evident.

As these broad patterns of change in the human dimensions of conservation unfolded in the 1970s and 1980s, the scientific foundations of conservation were again shifting. Taxonomy and systematics provided more robust estimates of the extent of species diversity and of its actual and potential loss. The subfield of island biogeography revealed principles governing the spatial distribution, persistence, and extinction of species, with important implications for land use and the establishment and management of protected areas. Genetics became an increasingly important component of conservation science as attention focused on the reproductive success of rare and endangered species and the viability of their populations, both in captivity and in the wild. Ecology moved away from its "classical paradigm," which emphasized single, stable, deterministic equilibria, and toward a view of ecosystems that emphasized flux, uncertainty, and contingency. Disturbances such as fire, flooding, and drought were incorporated into our understanding of long-term ecosystem dynamics and were shown to be important factors affecting species diversity. Increasingly, conservation strategies required the integration of knowledge from the many branches of biological science, involving various levels of biological organization.

The need to rethink conservation across disciplinary lines was driven not only by changes in the foundational sciences but also by changes in the environment itself. By the late 1970s, scientists and conservationists were alarmed by the escalating loss of genetic, species, and ecosystem diversity at the global scale. Of special concern was the accelerated destruction of the species-rich forests of the humid tropics. The advances in island biogeography revealed that ecosystems of all types were being fragmented by human activity, and that even the most effective protected areas were at risk due to their inadequate size and their isolation. Wildland managers increasingly understood that preservation alone was an inadequate management strategy, and that the loss of diversity and the disruption of ecological functions were intimately associated. Agricultural scientists, foresters, and other resource managers, too, were increasingly concerned about environmental degradation, the breakdown of ecosystem processes, the loss of diversity in humanized landscapes, and the human costs associated with these changes.

These concerns prompted the emergence in the mid-1980s of a new synthetic discipline, conservation biology, specifically devoted to the integration of scientific disciplines and other fields in the effort to understand, maintain, and restore

biological diversity (Meine *et al.*, 2006). Conservation biology has sought to address conservation problems within an evolutionary and ecological context, and to stimulate the traditional conservation professions to reassess their management methods and goals accordingly. The term *biodiversity* itself was coined in 1987 and has since been widely adopted by conservationists. The concepts of *sustainability* and *sustainable development* came into general usage during the same period, reflecting the complex challenge of integrating long-term social, economic, and environmental factors in assessing human demands and impacts on ecosystems. The integrating impulse was also evident in the recent emergence of restoration ecology, landscape ecology, sustainable agriculture, environmental history, environmental ethics, ecological economics, and other interdisciplinary fields.

Meanwhile, these changes in conservation science, philosophy, and policy prompted many in the traditional resource management fields to adopt more integrated approaches. In practical terms, this meant that as the conservation professions approached the new century, they sought to move away from narrow economic criteria for success and toward broader ecological standards; away from the mathematical desideratum of sustained yield of commodities and toward the more complex challenge of sustaining healthy ecosystems; away from the management of discrete components of the system and toward integrated ecosystem management; and away from an exclusive focus on the human goods and services provided by ecosystems and toward a focus on the biological diversity and ecological processes that sustain those goods and services (Minteer and Manning, 2003). These changes also began to redefine the meaning and value of wilderness, and to reintegrate wildlands within a broader approach to whole-landscape conservation. Whereas wilderness as traditionally defined existed apart from the humanized landscape (even while being preserved to meet human recreational and esthetic needs), wildlands at all spatial scales have become increasingly valued as repositories of biological diversity, as core protected areas and corridors within greater ecosystems, and as “controls” against which to compare the human impact on more intensively utilized lands.

These examples of increasing integration in conservation hearken back in many ways to the ecology-based synthesis that Aldo Leopold and others sought to articulate prior to the onset of the Cold War. Since then, the science of ecology has evolved, analytical tools and technologies have grown vastly more sophisticated, environmental threats have intensified, and the social and economic context of conservation has changed continually. Nevertheless, there is continuity between contemporary efforts to expand conservation’s cultural and natural connections and Leopold’s efforts to “enlarge the boundaries of the community to include soils, waters, plants, and animals” (Leopold, 1949).

Emerging Themes in Conservation

As in the past, conservation remains responsive to new demands, new information, and new realities. The sweeping changes that have reshaped the conservation movement since the mid-1980s will continue to alter both its social and

political dimensions and its practical field methods. Although we are still too much embedded in the present to recognize all these recent developments, we can identify important contrasts between emerging themes and conservation’s past practices.

In terms of its scientific foundations, conservation now seeks greater collaboration among the natural and social sciences, even while reaching beyond the sciences to build connections with philosophy, economics, history, literature, and the arts. Ecology continues to serve as a “fusion point” for the conservation-related sciences. In its conservation applications, ecology is bringing attention to a broader spectrum of species and to the processes that maintain diversity. To improve its chances of success, conservation continues to integrate the insights of ecology into the resource management professions, and to do so at various spatial and temporal scales. Conservationists increasingly focus on the resilience of coupled human and natural systems, and the recognition of ecosystem services as a means of encouraging and rewarding practices that enhance such resilience. The integrating fields of conservation biology, landscape ecology, restoration ecology, sustainable agriculture, environmental ethics, and ecological economics are now more solidly established (even while resisting the tendency toward specialization and reductionism to which even interdisciplinary fields are prone).

Emerging threats are making the conservationist’s task even more precarious. These include the rapid spread of invasive exotic species (especially as the human economy continues to globalize), the gathering momentum of global climate change, the increased presence of genetically modified organisms in the landscape, and the seemingly relentless fragmentation of habitats and ecosystems. At the same time, the sciences are being called on to illuminate the connections among biodiversity conservation, human health, and the well-being of human communities. Accordingly, the active weaving of conservation science into community-based ecological restoration programs promises to redefine the role and methodology of science in conservation.

The conservation movement continues to be shaped by overarching social and demographic trends. The growth in human population and in resource consumption rates remains a profound factor determining conservation’s future. To better inform that future, conservationists are seeking novel ways to integrate sustainable economies with effective protection, management, and restoration programs. Conservation planning efforts are expanding their reach across jurisdictional boundaries and across the landscape, recognizing the connections among wildlands, semiwild lands, “working” landscapes, and suburban and urban environments. Such cross-boundary forays have few precedents in conservation history and represent an important departure from the past.

In the past, conservation has also neglected human and cultural relationships to its own detriment. Increasingly conservationists recognize the need to integrate natural science, cultural traditions, and social relationships in the effort to protect and restore particular places. In seeking a better fit between the built environment and surrounding landscapes, conservationists have also begun to work more closely with architects, landscape architects, planners, and engineers to incorporate the emerging principles of conservation biology.

Meanwhile, the conservation movement itself continues to increase in diversity as individuals from varied backgrounds come into conservation as both professionals and amateurs. The environmental justice movement has, since the early 1990s, sought to broaden the political purview and demographics of the conservation movement. Local nongovernmental organizations are now regarded as key conservation players, and their role in conservation continues to grow. Although action at the international level remains necessary in addressing global threats to biodiversity and in supporting local initiatives, the assumption of greater local responsibility for ecosystem health is increasingly urgent. Community-based conservation projects, watershed restoration programs, land trusts, and other mechanisms are emerging to meet that need. As these trends continue, they seek to create not just an enhanced conservation movement, but an enduring culture of conservation. In doing so, they extend the long history of increasing citizen involvement in conservation.

Glossary

Definitive host For parasites with complex lifecycles, this is the host in which the parasite reproduces sexually (also called the *primary host*).

Epidemic Characterizes a sudden increase in parasite prevalence or intensity beyond that which is normally present.

Helminth One of several classes of parasitic worms: nematodes, cestodes, trematodes (monogeneans and digeneans), and acanthocephalans.

Intensity The number of parasites per infected host; a related measure, abundance, refers to the average parasite load of the entire population (including uninfected individuals).

Intermediate host For parasites with complex lifecycles, earlier parts of their life cycle are completed within intermediate hosts (also called the *secondary host*).

Prevalence The proportion of hosts in a population that are infected or diseased.

Reservoir host A host organism that can carry and transmit a parasite or pathogen to other host species while suffering little to no negative effects of disease.

R_0 The basic reproductive ratio of a parasite or pathogen; for a microparasite, this describes the number of new infections generated by a single infected host entering an entirely susceptible population; for a macroparasite, R_0 is the number of adult offspring produced by a single adult parasite over its lifespan.

Vector An animal that transmits parasites among definitive hosts; for example, mosquitoes are vectors of malaria.

Virulence Disease-induced mortality rate, or the harm caused by parasites to individual hosts.

Types of Parasites and Causes of Disease

Parasites are organisms that live in or on and obtain resources from a host, usually to the host's detriment. The terms parasite, pathogen and disease are often used interchangeably; however, disease refers to the pathogenic condition of a host, including the signs and symptoms of infection, whereas parasites and pathogens are the disease-causing agents. Infectious diseases can be caused either by microparasites (such as viruses, bacteria, protozoa, and fungi) or by larger macroparasites, including worms and arthropods. The distinction between macro- and microparasites is particularly useful to ecologists and epidemiologists because these groups differ in the degree of within-host replication, their ability to generate a lasting adaptive immune response, and how they are quantified. They also differ in their impacts on host populations (Table 1).

Disease outbreaks require the presence of a susceptible host population, an infectious pathogen, and favorable environmental conditions; these three factors are often referred to as the disease triangle (Wobeser, 2007). It follows that disease prevalence or infection intensity can increase when changing environmental conditions favor pathogen transmission or host susceptibility. In many cases, these environmental modifications are caused by human activities that lead to host crowding, habitat degradation, and host stress. Other environmental changes can cause novel pathogen introductions or enhance opportunities for cross-species transmission through changes in the composition of ecological communities or shifts in the geographic distribution of a host, pathogen, or vector species.

Basic Epidemiological Principles

Since the pioneering work of Anderson and May in the late 1970s, ecologists have shown increasing interest in the spread and impacts of parasites at the population and community levels. A general understanding of host–pathogen population ecology can illuminate problems in conservation biology ranging from detecting disease threats for endangered species to predicting how human impacts on landscapes will affect pathogen invasion and persistence. Epidemiologists quantify and model the spread of infectious diseases over time and space to identify parameters that influence their prevalence and population-level effects. Models are used in epidemiology to detail how processes operating at the level of individuals (such as infection, recovery, and death) translate into population-level patterns such as changes in the numbers of susceptible and infected hosts. Epidemiological models differ from models of other antagonistic interactions (such as between predators and prey) because pathogens and parasites do not necessarily kill their hosts. Also, a single host can be infected by many parasites at once, and recovered hosts can develop a long-term immunity to reinfection by some pathogens. It is useful to address models designed for micro- versus macroparasites separately to identify basic principles that govern parasite spread and quantify their effects on host populations.

Microparasites

Mathematical models for microparasites divide the host population into categories that reflect their stage of exposure,

Table 1 General characteristics, examples, and ecological properties of micro- and macroparasites

	<i>Microparasites</i>	<i>Macroparasites</i>
Representative taxa	Viruses, bacteria, protozoa, fungi, microsporidians	Helminths (e.g., nematodes, cestodes, and acanthocephalans), arthropods (e.g., mites, ticks, and lice)
Size and reproduction	Small, unicellular, short generation times and rapid replication within individual hosts	Large, multicellular, longer generation times, usually no direct replication within individual hosts
Transmission of infectious stages	Transmission <i>via</i> direct contact (e.g., venereal and vertical), vectors, or contaminated air/soil/water	Complex life cycles and intermediate hosts are common; can also be transmitted by vectors, close contact, or ingestion of material contaminated by feces
Effects on adaptive host immunity	In many cases, temporary or lasting host immunity develops quickly and protects against reinfection	Some acquired immunity, but antigenic diversity of parasites usually too high for host to mount lasting adaptive immune response
Effects on host fitness	Disease can be acute or chronic, may have strong effects on host survival or fecundity	Depends on the number of parasites within the host (can affect mortality or fecundity, usually chronic infection with cumulative, sublethal effects)
Quantification in host populations	Prevalence, seroprevalence, incidence	Prevalence, intensity, degree of aggregation in individual hosts
Frequency of epidemics	Common	Rare

including susceptible (*S*), infected (*I*), and recovered/immune (*R*) classes (Figure 1). These compartment models track changes in the number of hosts within each category, but ignore the number of parasites within each host. SIR models are commonly used in modeling directly transmitted microparasites of vertebrates, and have been developed and analyzed extensively (e.g., Anderson and May, 1991). The model shown in Figure 1 makes many assumptions that can be relaxed. For example, hosts are uninfected at birth, infection increases host mortality but does not affect host fecundity, and host populations are large enough that stochastic processes (random events that affect populations in unforeseeable ways) can be ignored. For pathogens for which hosts do not acquire immunity to reinfection (e.g., many plant and insect pathogens and vertebrate diseases such as tuberculosis and brucellosis), the recovered/immune class (*R*) is eliminated, and the equations simplify to a SI or SIS model.

The basic SIR model gives rise to several key principles that have consequences for the spread of infectious diseases in wild

populations. Of fundamental importance is a value called R_0 , the basic reproductive ratio of the pathogen. R_0 describes the initial rate of pathogen increase in a previously unexposed host population. This parameter is estimated by multiplying the expected number of new infections from a single infected host by the average duration of infectiousness. For the SIR model in Figure 1,

$$R_0 = \frac{\beta S}{\alpha + b + v} \quad (1)$$

R_0 must exceed 1.0 for a pathogen to invade and spread. The form of eqn (1) suggests that pathogens with relatively high transmission (β), low virulence (α), and low host recovery (v) are most likely to establish in host populations. For pathogens that can successfully invade, a common dynamical outcome is an “epidemic curve” (Figure 1, orange line), whereby the number of infected hosts firsts increases, then decreases as the pathogen spreads through the population. At the same time, the numbers of susceptible hosts decline as they transition to the infected class, and the number of recovered hosts gradually increases. The general shape of the epidemic curve produced by simple compartment models is mirrored by many real-world epidemics including influenza in humans and phocine distemper in harbor seals (reviewed in Anderson and May, 1991; Hudson *et al.*, 2002).

The SIR model shown in Figure 1 is useful for pathogens with density-dependent transmission, a process in which transmission (measured by the rate new susceptibles are infected per unit time) increases directly with host population density. Specifically, for density-dependent transmission there exists a threshold density, N_T , of hosts below which the pathogen cannot persist ($R_0 < 1$) in a host population. Assuming that the population is large and homogeneously mixed, this value is

$$N_T = \frac{\alpha + b + v}{\beta} \quad (2)$$

Pathogens that are highly virulent (high α) or have lower transmission (low β) are likely to require much higher host densities for establishment than those that are highly transmissible and relatively benign.

For some pathogens, transmission can remain relatively constant over a range of host densities, a process termed frequency-dependent transmission. A key result of frequency-dependent transmission is that there is no threshold density for pathogen invasion (so in theory, such pathogens can persist at arbitrarily low host densities). Pathogens spread by direct contact (such as touching), aerosol droplets (coughing or sneezing) or indirect contact (ingesting fecally contaminated food or water) are expected to show density-dependent transmission. By comparison, transmission of sexually transmitted diseases and some vector-borne diseases is thought to be frequency dependent. Importantly, field and experimental studies of pathogens affecting mice, voles, frogs, ladybird beetles, and wildflowers have shown that the transmission of most pathogens probably falls between these two extremes.

Analysis of simple microparasite models can generate important insights for considering pathogen risks to wild or captive populations. For example, models suggest that the population-level impacts of an infectious disease will depend

Figure 1 SIR compartment model for directly transmitted microparasitic disease. Diagram shows a population containing susceptible hosts (S), infected hosts that can transmit the parasite to others (I), and recovered or immune hosts that are no longer infected (R). Total host population size (N) = $S + I + R$. Susceptible hosts arise from birth or immunity loss at per capita rates a and γ , respectively. Individuals leave the susceptible class through natural mortality (rate b) or by acquiring the parasite at rate β after encountering an infected host. Hosts leave the infected category through natural death or disease-induced mortality (rates b and α , respectively) or through recovery (rate v) to an immune state. Differential equations that track changes in the numbers of susceptible, infected and recovered hosts are shown in the bottom left panel. Representative dynamics (changes in numbers over time) are graphed in the bottom right panel for the following parameter values: $a = 0.1$, $b = 0.05$, $\beta = 0.0006$, $\alpha = 0.3$, $v = 0.3$, $\gamma = 0.005$.

on several factors, including pathogen effects on individual host fitness. In general, for pathogens that lower host survival, those with intermediate virulence should have the largest negative impacts on host populations. If pathogens are too virulent, infected hosts will die before they cause many new infections, whereas nonvirulent pathogens can become highly prevalent but have minimal population-level impacts. For similar reasons, models also predict that sterilizing pathogens (those that reduce fecundity) can cause greater reductions in host population size than those that reduce survival (Anderson and May, 1991). Models can generate important predictions for pathogen control, including effects of vaccination or culling on the probability of pathogen eradication (see Intervention Methods).

Finally, the spread and impacts of pathogens will depend on a number of ecological and genetic heterogeneities. Unlike the simple homogeneous populations described in Figure 1, natural host populations tend to be stratified by age, sex, social rank, or clumped spatially due to fluctuating resources or habitat

fragmentation. This heterogeneity can have large impacts on pathogen transmission and, as a result, on disease control efforts. Heterogeneity also arises when pathogens can be transmitted between several different host species. For these multihost pathogens, some host species are reservoirs or amplifiers (their presence increases transmission of the pathogen), whereas others may lower transmission or be unusually susceptible to pathogen-induced mortality. The identity and abundance of different host species has been shown to be important in the transmission of plant diseases such as sudden oak death and animal diseases such as brucellosis, Lyme disease, and chytridiomycosis (see Habitat Management).

Macroparasites

In contrast to microparasites, macroparasites typically cause persistent infections (Table 1), in large part because the host's immune response is often incomplete or short-lived.

and persistence depend strongly on the rate of production of eggs or larval stages (λ), the rate at which parasites are consumed by hosts (β), and the survival of free-living infective stages ($1 - \mu$). The macroparasite model shown in **Figure 2** is also associated with a threshold host population necessary to sustain infection. Because larval macroparasites often have long-lived resistant stages and adult worms can live for years within their hosts, many macroparasites can persist at lower host population densities than directly transmitted microparasites.

The effects of macroparasite virulence on host population thresholds and their ability to regulate host populations depend on the degree of parasite aggregation. Parasites of intermediate virulence (α) will depress host density more than those of low or high virulence, and parasite impacts will be maximized when aggregation is low (so that parasites are distributed across a greater number of host individuals). Importantly, highly aggregated parasite distributions tend to stabilize host–macroparasite interactions, whereas random or regular parasite distributions tend to destabilize them, leading to population cycles in host and parasite abundance (**Figure 2**). When parasites reduce host fecundity (i.e., $\delta > 0$) this can further destabilize the host–parasite interaction and increase the probability of parasite-induced host population cycles.

Field studies also support a role for macroparasites in wildlife population dynamics, although their effects are often more subtle than the dramatic population declines seen in response to some microparasitic diseases. Perhaps the best evidence comes from a handful of field experiments where researchers treated a fraction of animals or a subset of populations with antiparasitic drugs. This approach has been useful in demonstrating impacts of nematode parasites on host survival and population sizes of feral Soay sheep, white-footed mice, and red grouse (with several examples reviewed in [Hudson et al., 2002](#)). In the case of red grouse, for example, cecal nematodes are only weakly aggregated among hosts and high parasite loads cause reduced fecundity in grouse. In addition, treating 20% or more of a local population to remove parasites was sufficient to halt periodic population crashes that occurred every 4–8 years (and see *Alternative Interventions*). This work suggests that macroparasites should not be overlooked as important causes of wildlife declines, either alone or together with other factors such as food limitation or harsh environmental conditions.

Case studies of macroparasite infections further emphasize the importance of sublethal effects of parasites for infection outcomes and host–parasite population dynamics. In the case of red grouse, for example, negative effects of cecal nematodes on host breeding success (and not survival) drive population cycles in abundance over time. Moreover, grouse that carry heavy infestations of cecal nematodes are more vulnerable to predation by red foxes and raptors. These effects of parasites on host fitness would be easy to miss, but their implications for host and parasite population dynamics are extremely important. In other examples, parasites have been observed to manipulate key behaviors of hosts as diverse as ants, amphipods, and fishes, making them behave in ways that increase their risk of being consumed by a predator and thereby improving the chances that the parasite will be transmitted to its definitive host ([Moore, 2002](#)). Another subtle effect of

parasitism occurs when infection by one parasite species affects host susceptibility to other pathogens. In the case of African buffalo, [Jolles et al. \(2005\)](#) showed that infections by parasitic worms were negatively associated with the probability of bovine tuberculosis infection, as might be expected if coinfecting animals experience sharp declines in body condition and greater mortality. The authors used a population dynamic model to show that high mortality of coinfecting hosts (as might be caused by failure of the immune system to adequately control both parasite types) qualitatively captured the observed patterns of disease in free-ranging buffalo populations. Thus, the sublethal and cumulative effects of parasites can impact host population dynamics and community-level interactions in substantial and unexpected ways.

Infectious Diseases as Threats to Biological Diversity

Introduced Parasites and Species Declines

Exotic diseases and parasites are increasingly recognized as important factors driving population declines and geographic range contractions in many organisms (**Table 2**). Owing to their high rates of spread and potentially devastating effects on host populations, a handful of pathogens are now considered the greatest threats to the survival of some endangered species. Parasitic organisms have been shown to impact host populations in a variety of ways. Most directly, disease-induced mortality can reduce host population sizes below a threshold necessary for maintenance and growth. In very small populations, differential mortality between male and female hosts can sufficiently distort sex ratios or shift host life history to affect future reproduction. This is illustrated by a facial tumor disease infecting Tasmanian devils that spreads when infectious cancer cells are transmitted through aggressive encounters, especially among older males. Mortality caused by this disease has resulted in declines of up to 50% in Tasmanian devil populations. Moreover, as older, more dominant males succumb to this disease, researchers have observed a shift in breeding phenology such that devils are reaching sexual maturity sooner and are breeding at a younger age than before the epidemic. Tasmanian devils may eventually come to rely on single, early reproductive bouts as opposed to engaging in multiple reproductive efforts over a longer time period.

A recently discovered terrestrial fungus, *Geomyces destructans*, causes White Nose Syndrome (WNS) in multiple bat species of the eastern United States (**Figure 3(a)**). Following initial reports in New York state in the winter of 2006–2007, WNS spread rapidly, devastating populations of the little brown bat (*Myotis lucifugus*) in eastern North America. Once among the most abundant bat species in North America, local population declines of *M. lucifugus* have exceeded 75%, with bat mortality reaching 100% in some hibernation caves. Perhaps one of the best-studied examples of parasite-induced population declines involves a chytrid fungus, *Batrachochytrium dendrobatidis*, which causes amphibian chytridiomycosis in hundreds of frogs, toads, and salamander species worldwide. Multiple amphibian populations from North America, Central America, South America, Australia, and several island

Table 2 Selected disease outbreaks associated with declines in natural populations

Host species	Disease (parasitic agent)	Location	Comments
<i>Plants</i>			
American chestnut (<i>Castanea dentata</i>)	Chestnut blight (<i>Cryphonectria parasitica</i>)	Eastern North America	Caused massive extinction of dominant hardwood species
Flowering dogwood (<i>Cornus florida</i>)	Anthrachnose bight (<i>Discula destructiva</i>)	North America	Fungus decimated dogwood populations throughout native range
Several native plant species	Fungal dieback (<i>Phytophthora cinnamoni</i>)	Western Australia	Responsible for large-scale diebacks and permanent plant community shifts
American elm (<i>Ulmus americana</i>)	Dutch elm disease (<i>Ceratocystis ulmi</i>)	North America	Pathogen introduced from Asia, spread by bark beetles
Multiple woody species including live oaks and tanoaks	Sudden oak death (<i>Phytophthora ramorum</i>)	Western North America	Introduced from Asia; wide host range
<i>Invertebrates</i>			
Elkhorn coral (<i>Acropora palmata</i>)	White pox disease (<i>Serratia marcescens</i>)	Caribbean Sea	Bacterial pathogen traced to human wastewater
Oysters (<i>Crassostrea virginica</i>)	Protozoan parasite (<i>Perkinsus marinus</i>)	Atlantic coast of North America	Warming ocean temperatures facilitated parasite spread along the coast
<i>Fish</i>			
Rainbow trout, salmon (<i>Salmo spp.</i>)	Whirling disease (<i>Myxobolus cerebralis</i>)	Montana	Introduced with stocked fish
Aral Sea sturgeon (<i>Acipenser nudiiventis</i>)	Monogenean trematode (<i>Nitzschia sturionis</i>)	Aral Sea, former USSR	Introduced with stocked Caspian sturgeon
<i>Amphibians</i>			
Multiple species of frogs, toads, salamanders	Digenean trematode (<i>Riberoia ondatrae</i>)	North America	Causes limb malformations during metamorphosis; linked with eutrophication
Multiple species of frogs, toads, salamanders	Saprolegniasis <i>Saprolegnia</i> spp (oomycete)	North America	Lethal to amphibian embryos; linked with increasing UV-B radiation, decreased rainfall and stocking nonnative fishes
<i>Reptiles</i>			
Desert tortoise (<i>Gopherus agassizii</i>)	Upper respiratory tract syndrome (<i>Mycoplasma agassizii</i>)	Mojave Desert	Introduction through released pets
<i>Birds</i>			
Hawaiian honeycreepers	Avian malaria (<i>Plasmodium relictum</i>)	Hawaii	Implicated in the extinction of several Hawaiian forest birds
House finches (<i>Carpodacus mexicanus</i>)	Bacterial conjunctivitis (<i>Mycoplasma gallisepticum</i>)	North America	Likely transfer from domesticated poultry
<i>Mammals</i>			
Harbor seals (<i>Phoca vitulina</i>)	Phocine distemper virus (<i>Morbillivirus</i>)	North Sea	Outbreaks likely initiated by contact with Harp seals
Sea otter, some wild felids, red fox	Toxoplasmosis (<i>Toxoplasma gondii</i>)	Pacific Ocean and the Pacific coast of North America	Associated with ground surface run-off contaminated by fecal matter from infected felines
Gorillas, Chimpanzees	Ebola virus (<i>Filoviridae</i>)	Multiple countries in Central and sub-Saharan Africa	Associated with severe population declines of wild primates

countries have experienced severe declines, with up to 50% of species vanishing over a matter of months in some stream communities of Central America (Figure 4).

In addition to causing precipitous declines of initially abundant host populations, parasites can also threaten already-endangered species with extinction. For example, critically endangered black-footed ferrets in western N. America succumbed to an outbreak of canine distemper in the late 1980s, with only 18 individuals remaining for population

recovery through vaccination and captive breeding efforts. It is important to keep in mind that such heavily endangered populations are not likely to sustain most parasites in the long run simply because remaining host populations are too small. This is particularly true for parasites that specialize on a single host species and for highly virulent parasites. However, parasites that infect multiple host species (i.e., generalist parasites) often pose the greatest conservation concern because they can persist in reservoir hosts and their transmission is not limited

Figure 3 Examples of infectious diseases that have caused population declines. (a) White nose syndrome caused by the fungus *Geomyces destructans* is illustrated by white spots on the noses and ear membranes of infected little brown bats (*Myotis lucifugus*); (b) Barley yellow dwarf virus causes yellowing of infected grasses compared to healthy grass; (c) Eurasian red squirrel (*Sciurus vulgaris*) severely infected by parapox virus introduced by gray squirrels into the UK; (d) Elkhorn coral (*Acropora palmata*) infected with white pox disease (white spots) caused by the human enteric bacterium *Serratia marcescens*.

by the small population sizes of many endangered species. As a case in point, rabies is a generalist pathogen that can be maintained in domesticated dog populations; in recent decades, rabies outbreaks have caused the near-extinction of local populations of endangered carnivores in parts of Africa, including African wild dogs and Ethiopian wolves. Additionally, theoretical studies suggest that parasites with frequency dependent transmission will cause severe problems for endangered species or species with small local population sizes (de Castro and Bolker, 2005) because they can continue to drive down host populations even after they have been drastically reduced in number.

Invasive Species and Pathogen Introductions

A number of introduced or exotic pathogens have caused catastrophic declines of plant and animal species. In epidemics where new pathogens are introduced into previously unexposed host populations, the disease often progresses rapidly through immunologically naive hosts and can cause mass mortalities. One of the best known examples is the introduction of the exotic malaria parasite *Plasmodium relictum* and its mosquito vector into the Hawaiian Islands. Although most nonnative birds on Hawaii showed a combination of resistance and tolerance to this infection, the parasite was

Figure 4 Amphibian chytridiomycosis can spread to native frog populations through contact with reservoir species such as the American bullfrog (*Lithobates catesbeianus*). Bullfrogs are disseminated globally to support the culinary industry for frog legs, and can be heavily infected with *Batrachochytrium dendrobatidis* (*Bd*). Bullfrogs that escape captivity can invade and contaminate new habitats with *Bd*. Chytridiomycosis epidemics can extirpate multiple amphibian species with dramatic effects on community structure and ecosystem function. Intervention efforts include continuous monitoring of amphibian populations, focused culling of established bullfrog populations, and alternative tactics such as augmenting antimicrobial peptides found on amphibian skin that can confer protection from *Bd*. The blue box (lower right) shows the mean percent of *Bd* growth inhibited by increasing concentrations of one antimicrobial peptide, esculentin. Amphibian species that are highly susceptible to lethal *Bd* infection have also been rescued to other locations for captive breeding and postepidemic reintroduction. Photo credits: bullfrog and cooked frog legs, Wikimedia Commons; infected *Atelopus zeteki* (center), Brenes R; inset *Bd* zoospores, Longcore JE; all other photos, Han BA).

extremely pathogenic to native bird species. Avian malaria epidemics throughout the Hawaiian Islands caused high mortality in the native birds, essentially clearing the lower island elevations of the native avifauna and contributing to the extinctions of several endemic bird species. In addition to species extirpations, introduced pathogens have facilitated drastic changes to community composition through invasion and displacement of native species. For example, Barley and Cereal Yellow Dwarf Viruses (Figure 3(b)) have enabled invasive annual grasses to outcompete and replace native perennial bunchgrasses in California. A parapox virus that is highly lethal to native red squirrels (Figure 3(c)) was introduced by invasive gray squirrels, and has accelerated the replacement of red squirrels by gray squirrels throughout much of the UK. Currently there is intensive research to determine whether invasive American bullfrogs are transmitting amphibian chytridiomycosis (Figure 4) to native amphibian

populations in western North America, Central, and South America. Dissemination of the amphibian chytrid fungus *via* invasive reservoir species could be particularly devastating in areas such as the Venezuelan Andes, one of the world's biodiversity hotspots for endemic amphibians.

Negative Community and Ecosystem Consequences

The negative impacts of parasites and pathogens extend beyond their direct effects on hosts. Host population declines can generate secondary effects that ripple through natural communities, in severe cases triggering secondary extinctions termed "extinction cascades." Examples of such community-wide effects have been reported from both marine and terrestrial ecosystems. For example, the disappearance of long-spined sea urchins (*Diadema antillarum*) throughout the

Caribbean Sea by an unidentified pathogen caused a shift from coral- to algae-dominated reef communities (Harvell *et al.*, 1999). Similarly, the virtual disappearance of the American chestnut caused by the introduced fungal pathogen *Endothia parasitica* led to the extinction of eight Lepidopteran species that fed predominantly on this tree species.

Direct and indirect effects of infectious diseases can also damage the way an ecosystem functions. For example, the extirpation of adult amphibians by chytridiomycosis in Panama was linked to dramatic declines in amphibian larvae in stream communities. In the absence of tadpoles as filter feeders, grazers, and detritivores, studies report dramatic decreases in the quality and quantity of fine organic particulate matter suspended in the water column (i.e., seston, made up of periphyton, tadpole feces and bacteria). These changes are likely to affect communities downstream, which receive an influx of energy through the particulate matter generated by headwater communities. Ecosystem impacts can occur even when host mortality or species declines are not apparent. For example, experimental manipulations of intact grassland communities demonstrate that infection by foliar fungal pathogens affects net primary productivity and soil respiration by reducing root biomass, photosynthetic capacity, and leaf longevity in multiple grasses (*Andropogon*, *Poa*, and *Schizachyrium* spp.) (Mitchell, 2003).

Anthropogenic Drivers of Disease Emergence in Nature

In recent decades, a growing number of pathogen outbreaks in natural systems have been attributed to human activities. In particular, economic development influences disease emergence through changes in land use and human population growth. These activities can increase the risk of pathogen spread in natural populations through habitat destruction or fragmentation, pollution or other forms of habitat degradation, climate change, and global commerce.

Loss and Fragmentation of Natural Habitats

Humans destroy natural habitats in a plethora of ways, many of which have been summarized under the term habitat fragmentation – the process of reduction and isolation of a continuous natural habitat into smaller patches. Habitat fragmentation is of great conservation importance because it affects native communities directly by removing individuals and their resources, and indirectly through changes in community composition and species interactions. In terms of host–pathogen interactions, the reduction or subdivision of a host population can allow hosts in some patches to escape infection, especially if patches are isolated. Furthermore, if remaining host subpopulations are relatively small they may fall below the critical host threshold required for disease persistence (N_T). Consequently, one possible result of habitat fragmentation may be the decline or extinction of a parasite. Conversely, it is also possible that hosts moving between habitat fragments will continue to spread infection. Between these two contrasting scenarios, the benefits of increasing

connectivity – namely the increased likelihood of species persistence and the potential for recolonization of locally extinct patches – appear to outweigh the potential costs of pathogen transmission between fragmented habitats on a landscape (McCallum and Dobson, 2002).

From a different perspective, habitat fragmentation can increase disease risks to native biota by providing opportunities for contact with domesticated crops, livestock, humans, and other native species crowded into adjacent habitats. For example, endangered red colobus monkeys living on the edge of forest fragments in Kibale National Park were exposed more frequently to multiple infections and had a higher prevalence and intensity of certain parasites, including harmful parasitic worms and protozoa, than monkeys living in the forest interior (Chapman *et al.*, 2006). The authors speculated that interactions with humans and domesticated species on the forest edge could cause greater exposure to some generalist parasites. Other work in this same region showed that forest fragmentation caused greater transmission of enteric bacteria among humans, livestock, and three wild primate species; this was partly associated with crop raiding behaviors of wild primates living in small fragments or on the edge of reserves.

Habitat Degradation and Pollution

Degradation of natural habitats takes many forms and has frequently been associated with pathogen outbreaks in wildlife and humans. Human activities such as logging, over-exploitation of game and fisheries, erosion, and pollution can trigger pathogen epidemics. For example, direct injury to trees as a result of logging can increase disease in native plant communities. Many scientists suggest that the phocine distemper epidemic that spread through the seal populations in the North Sea can be attributed to the depletion of the fish stocks (by commercial fishing) in the North Atlantic ocean, leading to aberrant migrations of harp seals seeking food. In addition, wastewater run-off (which includes human sewage and agricultural byproducts like pesticides and fertilizers) into the ocean has been linked with toxoplasmosis in southern sea otters along the California coast, aspergillosis in Gorgonian sea fans in the Gulf of Mexico, and white pox in Elkhorn coral in the Caribbean sea (Figure 3(d)) among other diseases (reviewed in Harvell *et al.*, 1999). Across the eastern seaboard of the United States and in the Gulf of Mexico, eutrophication due to excess run-off from agricultural fertilizers has led to outbreaks of *Pfiesteria piscicida*, an aggressive protozoan that kills large numbers of fish. In freshwater ecosystems, the spread and duration of avian cholera outbreaks in waterfowl populations is greatly facilitated by pollution from nutrient-rich run-off into wetlands. This disease, caused by the introduced bacterium *Pasteurella multocida*, has become the second most important cause of waterfowl die-offs in North America.

Global Climate Change and Disease

Because the development and transmission of many parasites depend on environmental conditions, it is not surprising that

anthropogenic climate change is expected to influence the distribution, prevalence, and severity of pathogens in natural ecosystems. A number of recent examples illustrate that even small changes in climate can speed up parasite generation times, shift the geographic ranges of both hosts and vectors, and propagate complex trophic cascades leading indirectly to disease emergence. In the Arctic, warming temperatures appear to enable lungworm parasites to mature twice as quickly within their slug intermediate host. Infection severity in muskoxen (the definitive host) is postulated to increase as climate continues to warm. Coral reef ecosystems are among the most severely impacted by small increases in temperature, which can trigger coral bleaching (expulsion of symbiotic algae from the coral) and enhance the growth rates of a suite of opportunistic infections that have led to massive coral die-offs. Although such ocean warming events can occur naturally in association with El Niño-Southern Oscillation events, their frequency and severity have increased during the past 20 years. As a result of warming oceans, Caribbean yellow band disease has increased in prevalence and virulence to endanger all four coral species in the genus *Montastraea*, the most important reef building corals of this region (Harvell *et al.*, 2009). Because so many marine organisms depend on habitat provided by coral reefs, and because reefs can take many years to recover, the consequences of such massive die-offs are profound and long-lasting.

As climate warms, species range shifts will also bring new species in contact with each other and with new parasites. For example, the distribution of some animal diseases (such as the previously discussed *P. relictum*, and *B. dendrobatidis*) could lead to declines of many endangered bird and amphibian species surviving in higher elevations. Since global climate impacts all biological interactions, some ecologists have noted that the net effects of changing climate can increase disease in some regions (as exemplified above) and decrease disease in others. Predicting changing biological interactions as a result of changing climatic conditions is therefore an increasingly important goal for scientists and wildlife managers.

Worldwide Commerce and Travel

Worldwide commerce and animal trafficking are probably the most important causes of new disease outbreaks in wildlife populations. This traffic, which has dramatically increased in the past few decades, includes international trade of live animal and plant stock for commercial breeding purposes, for zoos and animal parks, for the pet trade and hunting, and for laboratory research. The situation is exacerbated by the staggering amounts of international transport of fruit, vegetables, and various animal parts which can facilitate the spread of pathogens. For example, most of the major pathogens that cause disease epidemics in wild birds in North America were probably introduced by humans. Both avian cholera (a highly virulent disease caused by the bacterium *P. multocida*) and duck plague (caused by a herpesvirus) appeared first in domesticated bird flocks and spread to wild waterfowl. Today these diseases are responsible for the deaths of tens of thousands of wild waterfowl each year in the United States alone. Similarly, avian malaria was introduced to Hawaii with

imported birds, and brucellosis (caused by the bacterium *Brucella abortus*) was introduced to North America by domesticated livestock (and has since spread to wild deer, elk, and buffalo populations).

Disease spread into wildlife populations is further facilitated by the continual breakdown of barriers between farmed animals and wild animals. For example, aquaculture practices create crowded conditions where farmed Pacific salmon become heavily parasitized by sea lice (*Lepeophtheirus salmonis*). Wild juvenile salmon returning to open waters from spawning grounds travel migratory routes in close proximity to salmon farms, and become infected by sea lice on their way back out to the open sea. Similarly, there is concern that international demand for farmed bullfrogs is contributing to the spread of amphibian chytridiomycosis (Figure 4). As bullfrogs can carry very high pathogen loads with no clinical signs of infection, escaped bullfrogs that invade new habitats may transmit the chytrid fungus to native species that are less resistant to disease.

Sparse regulation of the growing exotic pet trade has exacerbated risks of novel pathogen introductions. Many exotic pets comprise a mix of captive reared and wild caught animals, which can facilitate the transmission of infectious diseases acquired from different environments. Currently there are no screening procedures enforced for exotic animals, especially for animals ordered over the internet. In 2007, the number of exotic animals imported into the US numbered over 37 million, reflecting a staggering diversity of reptiles, amphibians, rodents, primates, and various wild cat species.

Transport and commerce also pose a risk for the spread of invertebrate diseases due to the growing popularity of raising and releasing insects such as ants, ladybird beetles, bees, and butterflies for the purposes of biological control, pollination, education activities or for release at special events. Not surprisingly, the parasite communities of most insect species and disease risks for wild insect populations remain largely unknown. Honey bees are probably the best-studied insect species in terms of their infectious diseases, but disease threats have also caused concern for wild bumble bee species (*Bombus* spp.) in recent years. Since the 1990s, colonies of several native bumble bee species have been mass-produced and distributed for the pollination of greenhouse crops in North America. The movement of bumble bees from Europe to the US is thought to have introduced an exotic strain of a microsporidian parasite that is highly virulent to some North American bumble bees. This parasite appears to have caused the near-extinction of at least one bumble bee species (*Bombus affinis*). Furthermore, the prevalence of this and other pathogens was shown to be higher in commercially reared bumble bees than in nearby wild populations. Furthermore, infections in wild bees declined with increasing distance from industrial greenhouses, strongly implicating human rearing operations in the disease-induced declines of these pollinator species.

Positive Role for Pathogens in Biodiversity and Conservation

Although the risks they pose to threatened species are apparent, parasites and pathogens can also maintain biodiversity, in

part through their effects on the outcome of other species interactions. Indeed, recent advances in the field of disease ecology show that parasites can maintain diverse communities through their effects on competition, food web structure, and trophic interactions. Other work suggests that over longer timescales, parasites can promote evolutionary diversification among hosts. These interactions support the idea that parasites are integral components of ecological communities and can even mediate ecosystem processes. Although the conservation of parasites is almost never considered to be a priority, a key point highlighted by this section is that not all aspects of parasitism are necessarily negative; a strong argument can be made for conserving endemic parasites and pathogens.

Parasites, Species Interactions, and Biodiversity

One way that parasites can enhance biodiversity is by altering the outcome of competition between host species. In this case, generalist pathogens that are relatively benign to one species can lower the density of other hosts for which they are more pathogenic, potentially reversing the outcome of resource competition. Apparent competition is a related phenomenon whereby two or more hosts not directly competing for resources are affected by the same parasite to different degrees. In some cases, parasites shared between host species can threaten highly susceptible native species with extinction, as discussed in *Infectious Diseases as Threats to Biological Diversity* (e.g., red squirrel–gray squirrel parapoxvirus). In other cases, parasites can promote biodiversity by having disproportionate negative effects on otherwise dominant species, thus allowing many species to coexist at relatively low densities. Several case studies support the role of pathogens in determining plant and animal community structure and modifying the outcome of competition. For example, malaria parasites have been shown to facilitate coexistence between two *Anolis* lizard species on the Caribbean island of St Maarten; in parts of the island where lizard malaria is absent, only the dominant competitor was found, whereas the competitively inferior species could coexist at sites where malaria was present. Other studies found that pathogenic soil fungi can be more harmful to dominant tallgrass prairie species, facilitating the coexistence of less competitive species. Soil-borne diseases have also been implicated in the rate and direction of succession in plant communities and in determining patterns of seedling recruitment in tropical rain forests.

When parasites attack dominant herbivore species in a community, epidemics can cause major shifts in community composition through secondary effects on plant recruitment and abundance or on the density of predators and other natural enemies. One example involves the introduction of rinderpest in the Africa; this viral disease of cattle was introduced in the late 1800s and spread to native ungulate species including wildebeest and African buffalo, causing mortality rates of up to 80%. Starting in the 1950s, a vaccination campaign in cattle eventually eliminated the virus from wildlife, leading to a gradual rise in the numbers of wildebeest and other ungulate species. The growing numbers of herbivores affected species at other trophic levels: with the recovery of

wildebeest populations, predator populations increased (including lions and hyenas) and the biomass of vegetation (especially grasses) declined. This example illustrates how the effects of pathogens on dominant or keystone host species can propagate through food webs and alter community structure.

From a different perspective, evolutionary adaptations of hosts and pathogens over long timescales could increase biodiversity through cospeciation (the joint divergence of two or more interacting lineages) and phylogenetic diversification. For example, one comparative study of wild primates and their pathogens showed that primate host species from more diverse lineages harbored a greater number of parasite species (including viruses, protozoa, and helminths) (Nunn *et al.*, 2004). This pattern could be caused by an evolutionary arms race between hosts and pathogens, whereby hosts mount greater resistance against infection, and parasites evolve higher virulence and transmissibility. Other explanations are possible, however, including the idea that parasites infecting primates from more diverse lineages experience greater opportunities for diversification themselves through cross-species transmission and host shifting. As a final possibility, coextinctions of hosts and parasites might drive these associations. Parasite lineages could lose transmission opportunities and go extinct themselves as their hosts decline in population size, or as their geographic ranges shrink.

Pathogens and Host Genetic Diversity

In many ways, the maintenance of genetic diversity within species parallels the coexistence of multiple species in ecological communities and should enable hosts to evolve in response to changing environments and ecological perturbations. In terms of host–pathogen interactions, parasites are likely to be powerful selective agents because they can spread rapidly and cause significant negative effects on host fitness. Host species that are continually exposed to a diverse array of parasites should therefore harbor a variety of resistance alleles or a repertoire of inducible defenses. A growing number of examples from wild populations, including parasitic worms infecting Soay sheep and snails, and fungal pathogens affecting plants show how parasites can favor allelic diversity or sexual recombination in their hosts (Altizer and Pedersen, 2008).

Given the strong selective pressures imposed by parasites and the benefits of host resistance traits, an important question is why aren't all individuals resistant to infectious diseases? Simple host–parasite models show that genetic variation underlying host resistance traits can be maintained by balancing selection or by costs of resistance traits for host survival or reproduction. Balancing selection simply refers to processes that can maintain genetic variation over time, including heterozygote advantage, frequency-dependent selection, and selection pressures that fluctuate over time or space. For example, under frequency-dependent selection, rare host genotypes are resistant to pathogen genotypes that attack more common host types; this advantage held by rare alleles can lead to cycles in both host and parasite allelic frequencies over time, resulting in the maintenance of host genetic variation in the long-term. The phenomenon of parasites tracking

common host genotypes has been demonstrated by studies of parasitic trematodes infecting freshwater snails in New Zealand and bacterial pathogens of *Daphnia* in European ponds, and is critical for arguments concerning the role of parasites in favoring sexual reproduction in their hosts.

The major histocompatibility locus (MHC) in vertebrates provides a notable example of extreme polymorphism and diversity of rare alleles maintained by balancing selection. Immune proteins coded by MHC genes can recognize and bind to pathogen proteins (antigens) inside infected host cells, and transport these antigens to cell outer membranes. Here, they are presented to other immune cells that destroy infected host cells and initiate antibody production. Specific MHC molecules preferentially bind to specific pathogen peptides, and hence different MHC alleles confer resistance to different pathogens. In natural populations, MHC class I and II genes show enormous variation, and even species with low overall genetic diversity can show high genetic variation at MHC genes. In one extreme example, Aguilar *et al.* (2004) demonstrated high levels of variation across five MHC loci in a population of the San Nicolas Island fox with essentially no genetic diversity across selectively neutral loci. These findings led authors to conclude that intense balancing selection had maintained MHC variation in the face of past bottlenecks.

In plants, gene-for-gene coevolution has also been demonstrated to promote a high diversity of resistance and virulence alleles. For example, long-term field studies of the interaction between wild flax and flax rust in natural populations in Australia indicate that many alleles can persist among metapopulations, and the distribution of genotypes can change rapidly during individual epidemics. Collectively, these examples emphasize that pathogens commonly exert selection pressures on their hosts, in many cases leading to genetic heterogeneity over space and time.

Parasites and Ecosystem Function

Parasites and pathogens have long been excluded from studies of food webs (maps of feeding interactions in an ecological community) and ecosystem function (flows of energy and nutrients), in large part due to their small size and assumptions that they contribute little biomass to ecosystems. However, several recent studies have challenged this view by showing that parasites can dramatically alter the connectivity and stability of ecological food webs, and can represent a surprising fraction of biomass in real-world ecosystems. For example, parasites are involved in more food web links than predators in some estuarine and salt marsh ecosystems. Moreover, adding parasites to food webs increased measures of food web connectance (the number of actual links between species relative to the total links possible) by up to 93%. Indeed, parasites can account for 3–13% of the biomass of their free-living plant and animal counterparts in some estuarine ecosystems. Some parasitic worms like trematodes had biomass levels comparable to those of fishes and small arthropods, and their collective biomass was greater than that of top predators (namely shorebirds) (Kuris *et al.*, 2008). A similar study of plant fungal pathogens in a tallgrass prairie ecosystem showed that the estimated pathogen biomass was comparable

to that of herbivores, and that pathogen effects on grass biomass appeared to be stronger than the effects of herbivory (Mitchell, 2003). Other researchers have pointed out that host death caused by pathogens can liberate carbon and nutrients from host cells and tissues, increasing their turnover in natural ecosystems. Not surprisingly, however, the effects of pathogens on biogeochemical cycling remains relatively unexplored. More generally, a growing number of studies point to parasites as key players controlling properties of food webs and biomass production, and suggest that parasites should be viewed as essential components of ecosystem function rather than as nuisances that interfere with management objectives.

Parasites Can Inform Conservation of Threatened Species

Pathogens can reveal valuable information about host population size and movement in ways that enhance conservation efforts. A handful of case studies show that the evolution of some pathogens can be rapid enough to reveal cryptic host geographic isolation and historical contact patterns. For example, an analysis of sequence variation in the feline immunodeficiency viruses of cougars in western N. America (Biek *et al.*, 2006) showed that different pathogen lineages dominated in different parts of the cougars' range, indicating population structure in the host that could not be uncovered by analysis of molecular markers in the cougars themselves. Genetic analysis further revealed that the spatial occurrence of viral lineages is expanding, most likely due to increases in cougar population size. In another study, three species of whale lice revealed historical separation of populations of endangered right whales (Kaliszewska *et al.*, 2005). Genetic analyses of parasite mitochondrial DNA showed that whale populations in the North Atlantic, North Pacific, and southern oceans diverged several million years ago, following the formation of the Isthmus of Panama. High genetic diversity among lice in the currently small populations of North Atlantic right whales also indicated that their host population sizes probably numbered in the tens of thousands before the modern era of commercial whaling. This work illustrates the usefulness of pathogen molecular markers for understanding historical population size, contemporary population movements and geographic structuring of their hosts.

Managing Diseases and Biodiversity in the Future

Parasites and pathogens that pose significant threats to conservation programs can be divided roughly into two categories. The overwhelming majority of epidemics begin with the introduction of a disease into a naïve population. A second category of concern are cases where environmental changes (such as habitat loss and pollution) shift host relationships with endemic parasites. Effective disease prevention must therefore address both of these areas by limiting the introduction of novel pathogens and mitigating large-scale environmental changes that facilitate the emergence of endemic disease or cross-species transmission with domesticated species and humans. Monitoring and disease screening programs, quarantine and vaccination regimes, and attention to

captive breeding programs comprise common approaches to preventing or managing disease outbreaks in wild populations.

Monitoring Populations for Infection

Most pathogens are discovered after epidemics have already spread through wild populations. A powerful tool in the management of diseases is thus to monitor threatened populations for signs of infection before disease-induced mortality occurs. Several tools exist to monitor host populations and track the spread of an epidemic, and the efficacy of a monitoring program will increase with the number of host animals included in the screening (Wobeser, 2007).

Parasite prevalence and intensity are often monitored by examining blood, tissue, and fecal samples in animals. The presence of blood parasites (e.g., trypanosomes, malaria, and filarial nematodes), anemia, elevated leukocyte levels, and pathogen-specific antibodies can all be detected from relatively small volumes of blood. Antibody assays (e.g., enzyme-linked immunosorbent assay) can show evidence of current and past infection. Molecular techniques based on polymerase chain reaction tests can reveal the presence and intensity of infection in host blood or tissue by identifying and quantifying pathogen genetic material. In addition, many microbial pathogens can be cultured directly from tissue showing signs of infection or from swabs taken from the mouth, ears, eyes, nose, genitals, anus, or skin. Scans of feces will also provide information on the diversity of intestinal parasites in an individual as well as fecal egg counts per host as a measure of infection intensity.

Hosts that are hunted or culled for other purposes are frequently examined for internal and external parasites. Parasitic arthropods (e.g., ticks, mites, fleas, and biting dipterans) are also monitored because they represent key vectors for many infectious diseases and can decrease the condition of their hosts by drawing on host resources. Combining infection-related data from animals that are opportunistically sampled over a long time period can be useful for examining temporal trends. Long-term monitoring over large spatial scales is usually time consuming and expensive, but such studies often provide important information on the conditions leading to elevated disease prevalence, and are invaluable to developing effective disease management and prevention strategies for wild populations.

Assessing Disease Threats

Screening programs will verify the presence of a particular pathogen in a wild population, but do not provide information about population-level consequences resulting from infection. Epidemiological models outlined in the section on Basic Epidemiological Principles indicate that this determination requires information on both the prevalence of a pathogen (γ) and its effects on host fitness (α and δ). It is important to note that *post mortem* examinations are often performed to determine the effects of disease on individual hosts. However, the presence of a pathogen in dead animals does not necessarily indicate the cause of death, nor does it

reveal subtle disease effects on host behavior or fecundity. Ideally, captive or wild hosts should be monitored throughout the course of infection to compare survival and fecundity between infected and uninfected hosts. Experimental manipulation of parasite loads in natural populations remains the most direct way of assessing the effects of pathogens on host populations.

Intervention Methods

Historically, diseases in wild populations have drawn the attention of wildlife managers only after an epidemic severely threatened the host population or when a pathogen threatens agricultural crops or livestock. In general, the types of management regimes used to limit disease spread vary depending on the type of pathogen, the threat it poses to host populations, and the availability of financial resources. Management regimes also depend on the existence of agricultural or veterinary information and tools, which often do not exist for free-living plant and animal populations. That being said, pathogen outbreaks in recent years have allowed researchers to employ some of the more common intervention methods available and test their efficacy in reducing pathogen spread and impacts.

Vaccination, Culling, and Quarantine

Several intervention measures center on decreasing the number of contacts between susceptible and infectious host individuals to prevent new infections. Viral infections and, less frequently, bacterial infections in vertebrate animals can be effectively controlled by vaccinations, which confer a period of immunity and essentially transfer susceptible hosts directly to the resistant/immune class (see Microparasites and Figure 1). However, the cost of vaccinations and lack of testing (for safety and efficacy) in most wildlife species may severely limit the success of population-wide disease control plans. Epidemiological models can be helpful in determining where to concentrate finite vaccination resources, and what proportion of the population to target to limit or eradicate disease. A frequent goal of vaccination is to treat enough hosts to prevent pathogen invasion, or to achieve local eradication. This critical vaccination threshold is $1-1/R_0$, which reduces R_0 below 1. Vaccinations have been successfully administered to slow the spread of rabies in European foxes and North American raccoons, and vaccination of domesticated reservoir hosts (cattle and domestic dogs) has reduced the threats of rinderpest and canine distemper outbreaks in wild ungulates and carnivores in east Africa. A key benefit from vaccination is that even when susceptible hosts are not vaccinated they are less likely to be infected because they are surrounded by immune individuals. It is also important to note that even if too few hosts are vaccinated to eradicate a pathogen, low-coverage vaccination (of a small fraction of hosts) can still prevent local host extinction, as recently illustrated by vaccination of Ethiopian wolf populations against a potentially devastating rabies virus outbreak.

Culling is the removal of host individuals by lethal means. Culling can be indiscriminate or targeted solely toward infected individuals and is most often used when transmission is

believed to be density-dependent. The goal is to reduce host densities below the threshold needed for parasite persistence, N_T . Selective culling targeted toward infected individuals is analogous to intensifying parasite-induced mortality (α ; **Figure 1**). This strategy can effectively decrease disease prevalence and lower R_0 . Selective culling has been implemented to counter the spread of certain tree diseases (e.g., Dutch elm disease). Although less frequently applied to vertebrate populations, routine culling has been applied to some populations of Cape buffalo in South African national parks when individuals are found with tuberculosis. In Venezuela, invasive American bullfrogs are routinely culled to slow the spread of amphibian chytridiomycosis to native species (**Figure 4**).

Quarantine involves the isolation and care of infected individuals from a population currently experiencing an outbreak, with the goal of decreasing contact rates between infectious and susceptible individuals. Although commonly employed to slow or stop human disease outbreaks, this approach is less often applied to wild populations. An exception occurs when host populations are dangerously low in numbers such that every member may be of great value and worth rehabilitating. This was the case during a canine distemper epidemic in Wyoming black-footed ferrets (*noted in Introduced Parasites and Species Declines*), and a similar situation may arise if future epidemics affect endangered African apes, Ethiopian wolves, or African wild dog populations.

Alternative Interventions

Administering focused treatment regimes of antiparasitic drugs could be the best option for infectious diseases in some populations, although little quantitative data exist on the success of these approaches. Drugs and other forms of chemotherapy are most frequently administered for bacterial, fungal, helminth, and ectoparasitic infections. This method of disease control least effectively addresses the ultimate cause of a disease and may be extremely costly for population-wide control measures (e.g., systemic fungicides to counter tree blights). Other examples of targeted intervention include the treatment of mites causing mange in cheetahs, Arctic foxes, mountain gorillas, and wombats, but the long-term efficacy of these treatments is still unknown. Recently, researchers discovered that the microbial community and a wide array of antimicrobial peptides covering the surface of amphibian skin can confer protection against chytridiomycosis in some frog species (**Figure 4**). The possibility of augmenting this unique form of innate immunity to help conserve amphibian populations is an active area of research.

Habitat Management

Management regimes that address the ultimate causes of disease outbreaks have the greatest potential for removing disease threats but are also the most difficult to implement. Indeed, the ultimate causes of marine invertebrate diseases, namely, pollution and ocean temperature changes, are so global and diffuse in origin as to be impossible to confront in any single species management plan. Managing terrestrial habitats may alleviate some disease-related conservation problems. Two such examples are the proposed creation of a bovid-free land zone around Yellowstone National Park to prevent contact between bison and cattle, and

the removal of feral pigs from the Hawaiian Islands (because their activities increase mosquito-breeding areas and elevate the transmission of avian malaria).

An understanding of disease ecology is also pertinent to the design of habitat reserves. For example, how large should reserves be to prevent host crowding and limit disease transmission? Do corridors between reserves increase the threat of pathogen transfer among locations, or does host dispersal among habitats facilitate the spread of resistance genes or aid in parasite avoidance? Maintaining species richness and genetic diversity within reserves is also critical to limiting threats from disease. In particular, high species diversity may buffer natural communities from devastating epidemics, and habitats that are restored with genetically diverse stock may be less susceptible to pathogen invasion. In terms of host species diversity, this can be particularly important in slowing the spread of multihost pathogens. One hypothesis that has gained support from studies of both plant and animal communities is the dilution effect, which predicts a pattern whereby disease risk decreases with increasing host species diversity through one of several underlying mechanisms (*Keasing et al., 2006*). This buffering effect of host diversity can be especially important for pathogens spread by vectors that feed on several host species, but for which only a few host species effectively amplify the pathogen. The best-studied examples are the Lyme disease bacterium and West Nile virus, two pathogens that are transmitted between dozens of animal species by ticks and mosquitoes, respectively. In both cases, the presence of a diverse mammal and bird community, respectively, reduces the fraction of vectors that feed on highly competent hosts, and lowers infection prevalence in vectors. Thus, habitat management practices that maintain diverse vertebrate communities (such as larger reserve sizes and corridors that connect existing reserves) could lower the risk of pathogen transmission to wildlife and humans.

Concerns for Captive Breeding Programs

Conservation efforts rely increasingly on captive breeding programs to augment and restore free-living populations. Because captive animals are particularly susceptible to infections, pathogens represent a significant concern of captive breeding managers. Captive animals may acquire novel infections from unrelated species kept in the same pen, foster parents, or from individuals of the same species or closely related species. For example, captive African elephants kept in mixed collections have been infected with a lethal herpesvirus that occurs without disease symptoms in their Asian elephant pen mates. Captive-bred hatchlings of the endangered Mauritius pink pigeon contracted and succumbed to a herpesvirus infection that their foster parents (domestic rock doves) were carrying without ill effects. Several human diseases, such as measles, tuberculosis, herpesvirus, and influenza are highly virulent for nonhuman primates, especially gorillas, chimpanzees and other apes, which poses a concern for zoo and sanctuary animals exposed to potentially infected humans (and for wild animals exposed to ecotourism groups).

Many animals in captive breeding programs are often held close together, a practice that poses two disease-related risks.

First, animals are likely to become stressed and hence more susceptible to infection (particularly those that are territorial or normally persist at low densities in the wild). Second, crowding in pens or cages can elevate host densities above the threshold necessary for virulent pathogens to invade, and will also increase transmission rates (e.g., hosts may reinfect themselves by ingesting the eggs of their own parasitic nematodes released into their pen). Vector-borne diseases or parasites with complex life cycles may be less of a concern to captive breeding programs because of the likely absence of intermediate hosts (or vectors) that are necessary for transmission.

Finally, additional complications exacerbating disease problems in zoos and captive breeding programs stem from inbreeding depression, or the genetic impoverishment of a captive colony due to loss of diversity and the expression of deleterious recessive alleles. This loss of genetic variability leads to homogeneous captive populations that can be very susceptible to a variety of pathogens, as implicated in the high mortality that captive cheetah populations experienced due to a feline infectious peritonitis virus. Hence, genetic and ecological problems can operate in synergy to reduce population size and diminish heterozygosity, leading populations toward increased disease susceptibility, and possible extinction. In conclusion, as captive breeding programs expand, disease-related problems are likely to become even more prevalent and will require serious precautions including screening and treatment, suitable housing and animal care, and separating potentially infected individuals (including some humans) from healthy captive populations.

Equal Rights for Parasites?

Parasites are an integral part of life on earth, with their biodiversity projected to be significantly greater than the species richness of free-living hosts, but biologists have uncovered only a tiny percentage of this diversity. Many micro- and macroparasites that live uniquely on threatened host species could go extinct long before their hosts, and this poses a distinct threat for parasite extinction. As with most taxa, we do not have accurate numbers of how many species of parasitic organisms might be affected by future extinctions. But in contrast to many other threatened species, the conservation of parasites is virtually never considered a primary goal of conservation strategies. This is most likely due to their small body size and cryptic nature, and because parasites tend to draw the most public attention during epidemics where large numbers of hosts die from infection.

Many parasites have fascinating life cycles and have evolved incredible strategies for dispersing their progeny to new hosts. Some parasites have become sources of pharmaceutically important products; for example, a tick salivary gland component (calreticulin) has been used in dogs to treat thrombosis and heart disease. Perhaps more importantly, as humans disturb natural balances and break transmission barriers among species, pathogen outbreaks among rare or threatened host species will continue to occur. Because pathogens are a major factor promoting both genetic and species diversity in natural communities, conservation

strategies that result in the loss of native parasites might ultimately rob host populations of genetic diversity needed to respond to future epidemics. An important question that has yet to be answered is “do healthy populations have a diverse community of parasites?” If the answer is “yes,” then maintaining endemic parasite populations, and hence the ability of wild populations to respond evolutionarily to parasite-mediated selection, could be one of the best long-term strategies for mitigating the risks of infectious diseases.

Glossary

Benefit function (or curve) Function that describes the relationship between the expected conservation gains relative to level of investment.

Complementarity Extent to which a given area or action contributes to the conservation of biodiversity that is unrepresented in existing conservation areas or projects.

Conservation action Any activity aimed at improving conservation outcomes.

Conservation–investment curve Function describing the marginal change in conservation benefit with magnitude of investment.

Conservation prioritization Process aimed at determining how conservation resources can best be used to achieve stated objectives.

Convention on biological diversity International convention aimed at the conservation of biological diversity and the sustainable use of natural resources.

Cost-effectiveness analysis A type of cost–benefit analysis where the benefit cannot be expressed as a monetary value.

Decision analysis Discipline concerned with procedures for formally representing and assessing decisions in order to provide insight for decision makers.

Decision support tools General term for systems, often computer based, that use decision-analysis procedures to provide targeted information to inform decisions.

Ecoregion Generally large geographic areas defined by characteristic biodiversity that is largely distinct from other ecoregions.

Lookup tables Tabular data structures that allow users to describe the result of combining two or more variables. Used to avoid generating or using otherwise complex functions to describe the relationship between variables.

Marginal gain Economic concept that refers to the difference between the increase in benefit from investing in more of something relative to the cost of doing so.

Opportunity cost In conservation, value of alternative activities forgone at site in favor of conservation actions.

Restoration Process of repairing or renewing degraded habitat.

Return-on-investment analysis In conservation, process of comparing options in a way that explicitly considers the cost of each alternative.

ROI Abbreviation or shorthand for return on investment.

Species–area curve Relationship between area of habitat and number of species that it is expected to contain.

What is a Return-on-Investment (ROI) Analysis?

In the field of conservation, return-on-investment (commonly referred to simply as “ROI”) has come to be a rather general term for prioritization schemes that explicitly consider the cost of the alternatives being considered. These are in contrast to prioritization schemes based principally on the distribution of biodiversity (e.g., biodiversity hotspots; Myers *et al.*, 2000) or biodiversity and threats to it (e.g., Hoekstra *et al.*, 2005). The first published use of the term ROI referring to conservation prioritization was in 1998 (Bryant, 1998), but it was not until 2003 that the utility of ROI analysis for conservation prioritization began to be explored in earnest (O’Connor *et al.*, 2003). However, before ROI entered the popular lexicon, the phrase “getting the biggest bang for our buck” had been appearing in conservation publications with increasing frequency. The common element of both terminologies is that the expected return or outcome from a conservation action (The term

“action” is used here in a broad sense to include any allocation of resources aimed at improving conservation outcomes.) should be balanced against the cost of achieving that outcome.

In economic parlance, a return on investment is just that: the ratio of the amount of money you receive relative to the amount you need to invest in some endeavor (e.g., fund into a share portfolio or buying new equipment to improve the output of a business). The comparison between different options based on this ratio between investment and return is known as a cost–benefit analysis. Conservation ROI analyses belong to a general class of economic analysis known as cost-effectiveness analysis. Economists consider something to be a cost-effectiveness analysis rather than a cost–benefit analysis, when the outcome or return side of the equation is not monetized (i.e., expressed as a dollar value). This tends to be the case in conservation where our return might relate to the number of species saved or habitat protected. (The exception to this might be prioritizations involving

ecosystem services (Kareiva *et al.*, 2011)). Cost-effectiveness analysis was largely pioneered and is most widely used in health sciences, particularly looking at the effectiveness of different interventions where the desired metric might be human lives saved (e.g., deciding between passive case detection of tuberculosis or different levels of vaccination coverage; Edejer *et al.*, 2005).

A second use of the term ROI in conservation is associated with retrospective analyses of what conservation outcomes were delivered for a particular investment (e.g., Laycock *et al.*, 2009; Underwood *et al.*, 2009). Such analysis is more for accounting and communication purposes than prioritization of conservation actions, and it is not explored further in this article. Understanding the conservation outcomes that were actually realized as a result of conservation investment does, however, play an important role in more confidently estimating the expected return from future actions.

The Use of ROI Analysis in Conservation Prioritization

The main application of ROI analysis in conservation is in the field of conservation prioritization – tools or analysis that help us decide where and how to use conservation resources. Not all practitioners are comfortable with the use of the term prioritization, but if it is intended to inform or guide a decision about where or how conservation action takes place, then it is a prioritization scheme. ROI analysis has been applied to a number of different types of prioritization or resource-allocation problems. Probably the most common application has been to problems involving the spatial prioritization of conservation activities – in other words, “what places should be priorities for achieving desired conservation outcomes?” This question has been approached through ROI analysis at a global scale (e.g., Carwardine *et al.*, 2008a), regional scale (e.g., Moore *et al.*, 2004; Wilson *et al.*, 2006), and on national scales or below (e.g., Murdoch *et al.*, 2011). Although it is not always recognized as such, systematic conservation assessments (Margules and Pressey, 2000) are often close to ROI analyses, particularly when they are implemented using optimization software such as Marxan (Ball *et al.*, 2009) or Zonation (Moilanen and Kujala, 2008), whose algorithms work to minimize the cost of the set of places required to meet established conservation targets (Game and Grantham, 2008). If the cost data used with such software reflect the relative cost of taking conservation action in particular places, then this is essentially performing an ROI analysis (e.g., Carwardine *et al.*, 2008b).

The spatial analyses just described generally make the assumption that we are looking to apply a particular strategy at a chosen place. Although this assumption is more often than not implicit rather than explicit, it is necessary because it is hard to know the cost of working in a place without some idea of the activity you intend to take there. The most common type of analysis is based on prioritizing the establishment of some kind of conservation area (e.g., National parks). Protected areas make good fodder for analysis as the return or benefit from implementing them in a given place is potentially equal to the sum of the biodiversity present there. ROI analysis can also guide strategic decisions about investment between different activities or strategies. For example, Barlow *et al.* (2011) compare the cost-effectiveness of 18 different actions to

reduce human–tiger conflict in Bangladesh. Possible actions include killing problem tigers, collaring tigers, using different kinds of fences and deterrents, and establishing education programs, and their effectiveness is judged by the number of expected human and tiger lives saved per dollar spent. Although this sort of analysis is consistent with the use of cost-effectiveness analysis in health sciences, it has been less common in conservation, in part because conservation problems have rarely been framed clearly enough to allow a convincing benefit or return function to be expressed in the same units for different activities.

More recently, ROI analyses have also been used to help prioritize both strategy and place simultaneously – in other words, answering the question, “what should we do where?” (e.g., Wilson *et al.*, 2007; Klein *et al.*, 2010). The addition of both spatial and strategic decisions inevitably complicates analysis because the universe of potential alternatives is vastly greater, but it remains an equally suitable and perhaps more useful and realistic application of ROI. Of course, the division between these three classes of problem (spatial, strategic, and combined) is somewhat artificial as all three of these can be framed generally as prioritizing between alternative actions.

Enthusiasm for ROI analysis in conservation is growing. The motivation for its application comes from a number of directions. In part, the magnitude of issues facing global biodiversity so dwarfs the resources available that we recognize the need to make hard choices and to be extremely efficient with those resources we do have. Particularly in the nonprofit world, donors want to see that their money is achieving the greatest benefit it can – a point that is hard to argue without applying ROI analysis to investment decisions. The shift toward a more analytical and economic approach to conservation decision making also reflects a change in the skill set and experience of those involved in conservation. Historically, conservation biologists have typically been drawn from empirical ecology, with many having little formal training in decision analysis or economics, whereas today these are both essential pieces of most graduate conservation training. There is also an increasing willingness and, indeed, interest in conservation to emulate approaches from other fields that share similar motivations of efficient resource use (or simply the desire to make the biggest profit) and have dedicated substantial expertise to developing methodologies for doing so. In addition, the influence of an increasing interest in ROI among the academic conservation community should not be underestimated. As is typical, application in the field follows methodological advances in the literature. In the case of ROI, the role of academic publications has been not only to demonstrate and raise awareness about ROI methodologies but also to illustrate the importance of considering cost when prioritizing conservation work (in contrast to a number of high-profile conservation prioritization schemes that ignored cost; see Table 1).

The Value of ROI Analysis in Conservation

The ultimate motivation for employing ROI prioritization methods in conservation is more efficient conservation of biodiversity – essentially, more biodiversity protected. However, because the application of ROI to conservation

Table 1 Number of additional species protected for five measures of biodiversity by applying an ROI approach and four alternative priority setting approaches with a conservation budget of \$100 million per year over 20 years

Prioritization approach	Total species richness	Vertebrate species richness	Plant species richness	Endemic vertebrate richness	Threatened vertebrates	No. of distinct vertebrates
Return on investment	2524	341	2231	8	14	69
Areas with endemic species	1705	201	1504	6	8	45
Crisis biomes	1910	227	1683	3	10	23
Highly threatened species per dollar	1495	218	1276	4	9	43
Random	1571	208	1383	3	8	27

resource-allocation decisions is in its infancy, it is too soon to judge its effectiveness on this front. What makes a good decision is the process by which it was generated, not the ultimate outcome. From a philosophical standpoint, ROI analysis has a number of strengths relative to many existing approaches to conservation prioritization (whether this prioritization is explicit or not). These are mentioned throughout the article but are worth highlighting as they provide the foundation for the role and increasing use of ROI in conservation.

1. It acknowledges the importance of cost. ROI analysis reflects a recognition that the investment required to achieve conservation outcomes is important in deciding where and how we work. The resources available for conservation are limited, and directing them to the places with the most biodiversity does not necessarily lead to greatest protection of biodiversity. Conservation prioritizations have often overlooked this basic and fundamental point. This is despite numerous publications illustrating that ignoring cost in decisions about conservation priority is likely to lead to substantially less biodiversity being conserved than is possible for the same total resources (e.g., Bode *et al.*, 2008; Carwardine *et al.*, 2008a, b; Bottrill *et al.*, 2009). In other words, it is grossly inefficient to ignore cost. Similarly, high variation in the cost of taking conservation action (often orders of magnitude difference between alternatives) emphasizes the importance of considering cost in conservation decision making (Bode *et al.*, 2008; Murdoch *et al.*, 2011).
2. It encourages transparency about assumptions and values. Formulating ROI problems forces us to be explicit about the assumptions we are making. Being explicit about value judgments is a basic tenet of decision theory, and yet many conservation prioritizations and decision-support systems contain hidden assumptions and value judgments. For example, the widely used strategic planning process, Conservation Action Planning (TNC, 2007), uses a series of lookup tables to combine qualitative estimates of different aspects of threat to biodiversity (e.g., scope and severity) and produce an overall threat rank for the conservation feature of interest. These tables use rules like "One High or Two Medium threat rankings yield an Overall Threat Rank of Medium." Such statements contain many hidden values and risk tolerances, and yet their appropriateness is almost never considered before using

the Conservation Action Planning process. Although the term "value judgment" is commonly used in a pejorative sense, they are an important and perfectly reasonable part of conservation decision making, provided we are transparent about them. Going through an ROI prioritization exercise has often served to illustrate inconsistencies and biases in conservation preferences that were concealed by earlier prioritization schemes.

3. It encourages the consideration of diminishing returns. ROI analyses typically recognize that there are likely to be diminishing returns on our conservation actions. For example, the more area you protect in a given ecoregion, the smaller the marginal gain in conservation value. Although the notion of complementarity has been an important feature of systematic conservation planning for more than 30 years, the idea that the marginal benefit of conservation decreases even before some ideal target has been reached is relatively new. This is not dissimilar to the concept that biodiversity with the least protection should be a higher priority than those with more protection. The diminishing returns argument has both genuine ecological and value judgment underpinnings. On the ecological side, biodiversity conservation is subject to diminishing returns because of the species-area curve (whereby the number of new species increases at a declining rate with increasing area). On the value side, many believe that for the sake of ecological equality, places with greater protection represent a lower priority than those with less protection.
4. It encourages accountability. Decision-support tools are just that – support tools. They should not be so prescriptive as to limit the ability to capitalize on opportunities. However, an ROI analysis can serve to provide a transparent view of the value of particular opportunities, which will hopefully encourage decision makers to carefully justify decisions that have objectively poor ROI.

Framing ROI Problems

As self-evident and straightforward as it might sound, being clear about the question that an ROI analysis is intended to answer is often one of the most contentious steps in conducting ROI analyses. Clearly framing the problem involves being explicit about what resource-allocation decision the ROI

analysis is intended to support (the question it is trying to answer) and the appropriate conservation objective for this purpose. For example, a conservation organization or agency might want to identify places that maximize the protection of representative biodiversity for an available budget, prioritize projects that represent the most cost effective way to reduce the extinction risk of threatened species, or explore what agricultural policy measures are likely to have the highest biodiversity return per dollar. The universe of possible problems is large, but clarity at this stage is essential for defining appropriate return and investment functions.

Outside of academia, the conservation community has been distinctly poor at framing its work through explicit and well-formulated problems. In part, this is because of the legitimate challenge of distilling the multiple aims and elements that influence conservation decisions into a single objective statement. Other reasons are more culpable: There is a common perception that all conservation actions are working toward good ends and therefore clearly stated objectives are not necessary; we commonly employ less-rigorous and less-transparent methods of prioritization that do not demand well-framed problems; and vagueness about objectives avoids disagreement about mission and also makes accountability more challenging.

Objectives do not have to be a question of science. Rather, objectives should reflect values or the basic reason for caring about the decision at hand (e.g., a belief that all biodiversity should be equally protected, or a desire for the maintenance of particular species, etc.). Sometimes this basic reason will reflect legal obligations, perhaps resulting from the Convention on Biological Diversity, or endangered species legislation. Perceiving that objectives must be supported by scientific understanding has been a common trap for conservation biologists conducting prioritizations. Compared with ecological evidence, value judgments represent a less-disputable and more-legitimate reason for prioritizing one ecological feature over another.

Defining Conservation Return

Despite economic analyses being novel for most conservation biologists, ironically it has been the process of defining and accounting for conservation returns that have proved the most difficult piece of ROI analysis. Ecological systems are undeniably more complicated than financial systems, as are the motives of those involved in conservation. Distilling our substantial and yet incomplete knowledge of ecological systems into metrics that adequately capture the values and motivations of those involved will always be challenging. Poorly defined benefit functions have dogged many conservation prioritization schemes, representing probably the single most common reason for their failure to significantly influence subsequent conservation investment.

Conservation return is essentially the expected benefit toward some predefined objective of taking a particular conservation action. It can be thought of as equivalent to defining a dose-response model (Hajkowicz, 2009). Although the return side of the conservation ROI equation does not have to be expressed in terms of monetary value, it must be in the same units for all alternatives being considered, and it must be possible to

reliably estimate the likely return (or a surrogate for it) for each alternative being considered. This highlights two challenges – first, finding an appropriate metric; and second, estimating it. The former depends on having a clearly defined objective (see Framing ROI Problems) and on explicitly capturing the value systems of those using the prioritization. The latter will often depend on the creative use of surrogates or on expert opinion.

In the field of conservation, the basic building blocks of a return function are typically some surrogate for biodiversity – for example, the number of species in a particular taxonomic group (birds, mammals, or plants are common choices because they are relatively well studied) or habitat types. For large geographies where consistent data on species or habitats are lacking (like the continent of Africa), biodiversity might be represented by synthetic indices such as the Biodiversity Distinctiveness Index used by WWF (Burgess *et al.*, 2006). For more focused ROI prioritization problems, such as choosing between actions to conserve a threatened species, the basic return metric might relate to extinction risk of that species or the number of viable populations (e.g., Bode and Wintle, 2010) or, where projects across multiple species are being considered, the number of species expected to remain extant over a given time horizon (e.g., Joseph *et al.*, 2009). Recently, some conservation prioritizations have also included ecosystem services (e.g., freshwater provision or carbon sequestration) as fundamental elements of conservation return (e.g., Tallis and Polasky, 2009; Goldman *et al.*, 2010).

Benefit Functions and Diminishing Returns

Almost all conservation prioritizations will want to use more discriminate return functions than simply the number of species or habitat types. For example, we might care about protecting representative habitat types but are also likely to care about whether that habitat is intact or highly fragmented. A whole host of considerations influence how we value different elements of biodiversity, and these should be reflected in the return function as far as possible. To do so, we need to weight our base biodiversity metrics with these additional values but do so in a way that is consistent, transparent, and nonarbitrary. Species might be weighted by things such as taxonomic distinctiveness, rarity, cultural value, or financial value (e.g., Faith, 2008; Joseph *et al.*, 2009). Habitats might be weighted by condition, level of fragmentation, or the percent remaining (e.g., Lipsett-Moore *et al.*, 2010; Murdoch *et al.*, 2011).

Adding another layer of complexity is the fact that these weighted returns will almost never change linearly with changes in the variable under consideration. As an example, we might consider that very fragmented habitats have little conservation value, but once the level of fragmentation is even minimally reduced, conservation value increases rapidly (Figure 1). In practice, this means that elements contributing to weighted return functions are often further transformed according to a benefit curve. Defining these weightings and benefit curves is what it means to be explicit about value judgments.

The value of a conservation action is often considered dependent on what conservation has already occurred. For example, adding additional conservation areas to a region that is already well protected might be considered of less benefit than

conserving the same area in a region with very little existing protection. This concept is known as diminishing returns. Diminishing returns are frequently implemented in ROI analysis through the use of a species–area curve (but see, Smith, 2010). The details of this curve and procedure are described below (see ROI with Diminishing Returns), but it is noteworthy that the actual form of the species–area curve is relatively unimportant for the function it performs (Bode and Murdoch, 2009).

Probability of Success

In nearly all prioritization situations, there is likely to be some uncertainty in the expected conservation return from a given action. Of particular concern are events or risks that are beyond the control of conservation management and yet are likely to influence the success of conservation interventions. In ROI analyses, these risks are typically expressed as a probability of success. This is the likelihood that a particular chosen conservation alternative will deliver the return expected of it. Probabilities are logically multiplicative, such that the expected return should be calculated as $E = R \times P$, where R is the return function derived from the elements described above and P is the probability of success. The probability of success might be derived

Figure 1 Conservation benefit function applied to habitat fragmentation within African ecoregions during an ROI analysis conducted by The Nature Conservancy (Tear *et al.*, unpublished). To give the conservation return in each ecoregion, a base measure of biodiversity was multiplied by the level of habitat fragmentation transformed according to the modified exponential function, $ae^{(b/F)}$, where F is the inverse of fragmentation extent in the ecoregion, and a and b are constants that reflect the value judgments of The Nature Conservancy staff with respect to habitat fragmentation and conservation value.

from the assessment of experts; for example, Joseph *et al.* (2009) asked experts to estimate the likelihood of different factors that might contribute to the failure of threatened species recovery projects (e.g., operational, legal, political, and social) and then combined these to calculate an overall probability of success. Game *et al.* (2008) used models of the risk of catastrophic bleaching to determine the likely success of protecting different reefs on the Great Barrier Reef, Australia. And Tear *et al.* (unpublished) used the Ibrahim Index of African Governance (<http://www.moibrahimfoundation.org/en/section/the-ibrahim-index>) as a surrogate for the probability of successful conservation projects in different African countries.

Estimating Investment

It goes without saying that a well-thought-out estimate of the costs associated with the alternatives under consideration is a prerequisite for an ROI analysis. Although some ROI papers use terms such as realistic or thorough when setting standards for cost data, these are desirable but not necessary. Most important is that the cost data used reflect something that is relevant to the decisions at hand, and that the relative cost of each alternative under consideration can be reliably estimated.

Numerous elements contribute to the cost of taking a conservation action somewhere (Naidoo *et al.*, 2006). (Conservation biologists tend to use cost in a looser sense than economists would be comfortable with. For example, Klein *et al.* (2010) define the opportunity cost of establishing marine protected areas as equivalent to forgone revenue (quantity $\times$ price), a common convention in conservation. In reality, economists would define opportunity cost as net benefits forgone, which is profit not revenue.) Although actual costs are undeniably complicated to estimate, cost surrogates useful for prioritizations are often surprisingly easy to estimate because there are typically limited measures available. At large scales, there will often only be a couple of options. At finer scales, cost data will often depend on either the creative use of surrogates or expert opinion. Ideally, in estimating the investment required of alternative conservation options, we would be able to draw on and extrapolate from actual costs of conservation, and some data sets do (e.g., Balmford *et al.*, 2004). Unfortunately, the field of conservation has not been good at tracking the actual costs associated with different conservation actions in different places, so despite many years of conservation activity we rarely have good data to draw from. Table 2 identifies some typical types of costs and surrogate measures for them that have been employed during ROI prioritizations.

Table 2 Different types of cost data used during conservation prioritizations, with published examples

Type of cost	Example data or surrogate
Management cost	Modeled annual management costs of terrestrial protected areas (Moore <i>et al.</i> , 2004; Bode <i>et al.</i> , 2008) Modeled annual management costs of marine protected areas (Balmford <i>et al.</i> , 2004)
Opportunity cost	Predicted management costs associated with threatened species recovery projects (Joseph <i>et al.</i> , 2009) Expected agricultural productivity (Naidoo and Iwamura, 2007) Historical fishing revenue (Game <i>et al.</i> , 2008; Klein <i>et al.</i> , 2010)
Purchase cost	Current market value of land (Murdoch <i>et al.</i> , 2011)
Transaction cost	The number of language groups with which negotiation would need to happen (Lipsett-Moore <i>et al.</i> , 2010)

ROI Analysis

The following examples illustrate a variety of ROI analyses, along with the conservation prioritization question they were intended to inform. For each example, there is a description of the problem, the return model, the investment model, and the equation or algorithm used to generate a solution. They are presented roughly in order of increasing analysis complexity.

Prioritizing between Restoration Strategies

The most straightforward ROI analysis is developing a simple ROI rank of alternatives. This is essentially answering the question, "What is the most cost-effective alternative in which to invest the next dollar?" Goldstein *et al.* (2008) describe the use of an ROI analysis to rank six alternative approaches to the reforestation of montane pastureland in Hawaii. Each restoration approach represents a different set of land-use transitions. Based on an average 200 ha parcel in their study area, the authors model conservation return as the expected increase in

Figure 2 ROI ratio for each restoration transition for native forest birds (filled bars) and understory plants (open bars). Reproduced from Goldstein JH, Pejchar L, and Daily GC (2008) Using return-on-investment to guide restoration: A case study from Hawaii. *Conservation Letters* 1: 236–243, with permission from Wiley.

mean native bird and plant understory density under each of the six alternative restoration approaches. Required investment was modeled as the net present value of expected restoration management over 50 years. To calculate the ROI of each restoration approach, the authors simply divided the expected increase in native bird and understory plant density by the expected cost of that restoration transition pathway (see Figure 2).

ROI with Diminishing Returns

To demonstrate the value of even a simple ROI analysis, Murdoch *et al.* (2007) calculated the expected ROI of buying land for conservation in each of the 21 North American ecoregions that are dominated by temperate broadleaf and mixed forests. Conservation return was defined as the number of plant species conserved across all ecoregions. Required investment was assumed to be equivalent to the mean per acre land value in each ecoregion. The expected number of species protected per acre purchased depends on not only how many species are present in each ecoregion but also how much of the ecoregion is already protected (the diminishing returns element). In ecoregions that are already well protected, new protected areas will add fewer additional species. To accommodate these diminishing returns, the authors weighted the expected return by the species–areas curve. Thus, the relationship between the number of species conserved, S , and the area protected, A , is given by $S = \alpha A^z$, where α is an ecoregion specific constant based on the number of species present in the ecoregion, and $z = 0.2$, an established value for the rate of accumulation of plant species on continental landmasses. The marginal return (number of species) of protecting additional land in each ecoregion is given by the derivative of the species–area equation with respect to A :

$$\frac{dS}{dA} = z\alpha A^{z-1}$$

With an estimate of species accumulation with area and knowledge of the cost per unit of land area, it is possible to define an ROI curve (Figure 3). In the case of Murdoch *et al.* (2007), this is a species–investment curve because species is their unit of return. Based on where each ecoregion starts on that curve, the authors rank each ecoregion

Figure 3 Species–investment curves for five US ecoregions dominated by temperate broadleaf and mixed forests. Reproduced from Murdoch W, Polasky S, Wilson KA, Possingham HP, Kareiva P, and Shaw R (2007) Maximizing return on investment in conservation. *Biological Conservation* 139: 375–388.

Table 3 Return on investment by ecoregion based on the increase in plant species conserved per \$1 million investment

Ecoregion	Plant richness	Total area (million ha)	Land value (\$ ha ⁻¹)	ROI: Plant species conserved per \$1 million	Rank	Current protected area (ha)	ROI: Increase in plant species conserved per \$1 million investment	Rank
North Central Tillplain	2243	12.316	3990.75	6.94	12	0	258.54	1

based on the increased number of plant species expected to be conserved per million dollars invested in that ecoregion (Table 3).

ROI Considering Threat

The expected benefit of a conservation action depends not only on what conservation already exists, but also on what would be expected to happen in the absence of that action. Protection of habitat that prevents clearing that would have happened otherwise is arguably more valuable than protecting a piece of habitat that is unlikely to be cleared regardless of conservation investment. This concept is used by Murdoch *et al.* (2011) in conducting an ROI analysis to establish the most-effective cadastral parcels to purchase in order to conserve 10% of all 77 ecosystem types that compose the grasslands of Argentina. Ten percent of Argentina's grassland is equivalent to 15.5 million ha.

In the analysis of Murdoch *et al.* (2011), the expected conservation return from purchasing a cadastral parcel for conservation depends not only on a diminishing returns function according to how much of that ecosystem type is already protected but also on the risk of that parcel being converted. Because this risk is assumed to be entirely mitigated once the parcel is protected, the return for each parcel is defined as the intrinsic value of the parcel multiplied by the probability that the parcel will be converted if not protected. Conversion risk for each parcel was estimated based on the human footprint dataset. The purchase or investment cost for each parcel was defined as the per hectare cost of land based on mean real estate values for that parcel. The analysis was used to identify spatial priorities for increasing grassland protection to 15.5 million ha. For illustrative purposes, the authors compared priorities identified using the ROI approach to those identified using two other plausible prioritization strategies; selecting those areas with the highest conservation return regardless of cost, and selecting the

Figure 4 Priority conservation areas resulting from applying each of three prioritization strategies to achieve the goal of 15.5 million new ha conserved (10% of total grasslands). (a) Maximize benefit – selecting those areas with the highest conservation return regardless of cost; (b) minimize cost – selecting the cheapest areas regardless of conservation return; (c) ROI. Existing protected areas (0.5 million ha) are shown in red. Reproduced from Murdoch W, Ranganathan J, Polasky S, and Regetz J (2011) Using return on investment to maximize conservation effectiveness in Argentine grasslands. *Proceedings of the National Academy of Sciences of the United States of America* 107: 20855–20862, with permission from PNAS.

cheapest areas regardless of conservation return. The substantial difference in priority between these three approaches is shown in Figure 4.

ROI with Actions and Locations

The preceding examples use ROI analysis either to prioritize actions (restoration approaches) without specific reference to the location where this will occur or to prioritize the location for an already established action (land purchase). ROI analysis can also be used to prioritize both action and location simultaneously, essentially answering the question, “What should we do where?”

The reefs of the Coral Triangle are threatened by both unsustainable and damaging fishing practices and by runoff from the adjacent land containing sediment, nutrients, and other organic pollutants. The threat from fishing can be ameliorated through the establishment of marine protected areas, but mitigating the threat posed from runoff requires terrestrial conservation measures in coastal catchments. Klein *et al.* (2010) describe an ROI analysis to prioritize conservation investment between these two activities across the 16 marine ecoregions of the Coral Triangle. To model conservation return, the authors use a formula developed by Halpern *et al.* (2008) to estimate the overall level of threat from both marine and terrestrial sources

being experienced by reefs in each ecoregion. Assuming that these threats reduce linearly as the proportion of the ecoregion protected increases, conservation return per action per ecoregion (or ecoaction, as the authors call them) is defined as the expected reduction in overall threat to reefs either from protecting either an area of reef or land in that ecoregion. The cost of investing in each possible ecoaction is calculated as the sum of the annual management and opportunities costs associated with marine and terrestrial protected areas in those locations. Protected-area management costs were calculated based on modes developed by Balmford *et al.* (2004) and Moore *et al.* (2004) and subsequently generalized by Bode *et al.* (2008), whereas opportunity costs are based on expected agricultural profitability in terrestrial areas (Naidoo and Iwamura, 2007) and expected catch value in marine areas. Each action in each ecoregion was then ranked according to its expected ROI (Figure 5).

This ranking provides two useful pieces of information for prioritization. First, it provides an ROI comparison of marine versus terrestrial action (for marine conservation) within each ecoregion. Second, it provides a comparison of the expected ROI (both marine and terrestrial) between ecoregions across the Coral Triangle. With the exception of one ecoregion (northern Philippines), marine protection always has a higher ROI than terrestrial protection within an ecoregion. When ROI ranks are compared across all

Figure 5 Ecoaction rankings indicate their relative priority for coral reef conservation investment across the Coral Triangle (taller bar, higher rank). Letters labeling ecoregions follow the ranking order for marine conservation (i.e., ecoregion A ranks highest for marine conservation). Adapted from Klein CJ, Ban NC, Halpern BS, *et al.* (2010) Prioritizing land and sea conservation investments to protect coral reefs. *PLoS One* 5: e12431.

ecoregions of the Coral Triangle, however, terrestrial action in some ecoregions often has a higher ROI than marine action in others.

Using ROI Analysis to Develop an Optimal Allocation Schedule

Threatened Species Recovery Projects with a Fixed Budget and Time

Conservation agencies often have fixed annual budgets with which to allocate and no shortage of competing demands. For example, New Zealand has more than 2000 species that are listed as threatened and for which the Department of Conservation has the task of improving conservation status. Joseph *et al.* (2009) described the use of an ROI analysis to help the New Zealand Department of Conservation prioritize threatened species recovery projects, with the objective of improving the security of the greatest possible number of unique species. The term security refers to security from extinction in the wild (achieved when available evidence indicates there is a viable population), and uniqueness of a species is measured as its taxonomic distinctiveness. The analysis compared potential projects for 32 different species for which the current annual budget for management across all species was NZD \$512,000. Given the time required for threatened species recovery projects, the analysis looked at the optimal allocation of resources over the next 50 years – a total budget (with discounting) of \$20,269,096.

Each species i , was given a weighting W_i , according to its taxonomic distinctiveness. Joseph *et al.* (2009) then used experts to estimate the expected return from projects for each species. The biodiversity benefit of the project, B_i , is the difference between the probability of the species being secure in 50 years with, P_i , and without, P_0 , the implementation of that

project; $B_i = P_i - P_0$. The same experts were also asked to estimate the probability of success for the project, S_i , and the cost for the project over 50 years, C_i . The ROI for project i (or project efficiency in the authors' language) is calculated as $ROI_i = (B_i \times W_i \times S_i) / C_i$. The authors use the ROI rank to work out which projects should be funded over the 50 years with the given budget in order to secure the greatest number of threatened species. They compare the results to other allocation approaches (Table 4).

Land Purchase Priorities with a Fixed Budget

The preceding examples all rank a series of alternative options based on their current expected ROI. As discussed, however, an available alternative's ROI depends to some extent on what conservation has already taken place. This means that ROI will change as we invest conservation resources (diminish as conservation takes place), and it might lead to changes in the ROI rank of options following some investment. If we have a known conservation budget, we can use the conservation-investment curves for each alternative to calculate the optimal allocation of this budget to different alternatives. In its simplest form, this optimal allocation proceeds by investing in the alternative with the highest ROI until another alternative is expected to have a higher ROI, at which point investment is switched to this alternative – the same process being repeated until the entire budget is allocated. The alternative with the steepest conservation-investment curve according to current investment levels has the highest ROI.

Murdoch *et al.* (2007) extended their temperate broadleaf forest ecoregion analysis (see ROI with Diminishing Returns) to define the optimal allocation schedule across ecoregions for five different total budgets. These allocations are those that are expected to protect the greatest number of plant species across all ecoregions for that total budget (Table 5).

Allocation Across Actions and Locations

To demonstrate how an ROI framework can be used to inform the optimal allocation of resources across both actions and locations, Wilson *et al.* (2007) calculated the optimal investment of conservation resources to address the threats faced by 17 of the world's Mediterranean ecoregions. Each ecoregion has a different mixture of key threats and different candidate actions to address them. In total, they evaluated 51 ecoregion-conservation action combinations (ecoactions). With the objective of maximizing the total number of Mediterranean vertebrates and vascular plants conserved, the authors allocate a hypothetical budget of US\$100 million annually for 20 years to reduce threats to species in the 17 ecoregions. For each ecoaction combination, a variety of data (expert input, literature review, and analysis of regional datasets) was used to estimate not only the number of at-risk species likely to be conserved as a result of that action but also the cost of successfully implementing the action. Together with the expected rate of diminishing returns, these estimates were used to generate conservation-investment curves for each ecoaction combination (Figure 6).

At any point in time, the optimal allocation of resources across ecoactions is determined by an interplay between

Table 4 New Zealand threatened species recovery projects ranked by weighted ROI, unweighted ROI, cost, taxonomic distinctiveness, and threat status

Species	Weighted ROI rank	Unweighted ROI rank	Cost rank	Distinctiveness rank	Threat status rank

(1) the existing level of conservation investment in that ecoaction, (2) the relationship between additional area invested in each ecoaction and the biodiversity benefit, and (3) the cost of this investment. Because of the dependency between the optimal ecoaction and the investment taking place in other ecoactions, solving for a truly optimal allocation schedule through time among such a large number of ecoactions is computationally intractable (Costello and Polasky, 2004; Wilson *et al.*, 2006). With a smaller number of options ($\sim <8$), it is possible to use methods such as stochastic dynamic programming to find the optimal solution, although “rule of thumb” or heuristic algorithms can be used to solve large problems quickly and have been found to closely approximate the optimal investment schedule (Wilson *et al.*, 2006). This heuristic used by Wilson *et al.* (2007), “maximizes short-term gain” by directing funds each year to ecoactions that provide the greatest short-term increase in biodiversity benefit per dollar invested. Using this heuristic, the authors generate an investment schedule that allocated some money to 30 different ecoactions over the 20-year period; it is expected to result in the greatest number of Mediterranean species conserved (Table 6).

Extensions and Variations

The preceding examples represent conventional applications of ROI analysis in conservation prioritization. ROI is, however, a flexible tool that can be used to support a wide range of conservation-prioritization and resource-allocation problems. The following examples illustrate some extensions and variations of ROI analysis for other situations that are likely to be commonly encountered in conservation.

ROI with Dependent Returns

Using ROI to optimally allocate resources through time recognizes that there is a relationship between the value of one action and the investment already occurring in others. However, each conservation option is still assumed to be independent (i.e., the return and required investment do not depend on what other actions are being taken). In reality, such dependencies commonly exist. Biodiversity often faces multiple threats in the same place, and conserving it might require multiple actions to ameliorate these threats. These dependencies can be incorporated into an ROI analysis. Evans *et al.* (2011) explore the situation in which

Table 5 Optimal budget allocation across ecoregions

Ecoregion	Total budget allocation				
	\$100 million	\$200 million	\$300 million	\$400 million	\$500 million
North Central Tillplain	\$37,651,522	\$49,584,149	\$59,853,018	\$69,612,043	\$79,371,069

Figure 6 Conservation-investment curves for three conservation actions: *Phytophthora* management, invasive predator control, and revegetation in the Swan Coastal Plain scrub and woodlands ecoregion of Australia. The area of conservation interest is illustrated by the curve to the left of the circles, comprising the area already receiving the action (denoted by the solid lines between the origin and the squares) and the area requiring the action (denoted by the dashed lines between the squares and the circles). Adapted from Wilson KA, Underwood EC, Morrison SA, *et al.* (2007) Conserving biodiversity efficiently: What to do, where, and when. *PLoS Biology* 5: 1850–1861.

some conservation benefits cannot be realized unless two actions are taken in the same place – in this case, protecting threatened Australian species, which requires both foxes and rabbits to be controlled in order to benefit. Although controlling foxes and rabbits on their own will benefit a wide range of threatened species, some species require both. Explicitly incorporating these dependent benefits into an ROI framework resulted in a far more cost-effective conservation prioritization than considering them only independently (Figure 7). The results also emphasize the importance of considering the full range of threatening processes when estimating expected conservation returns.

Relationship Between Cost, Risk, and Complementarity

Another type of dependency that is more familiar to conservation planners is the notion of complementarity. When trying to efficiently conserve the range of biodiversity that exists in a region, the value of taking action to conserve a given location depends on what other locations are already protected and the species conserved there. Although this dependency represents a substantial computational challenge, there is freely available conservation software, such as Marxan (Ball *et al.*, 2009) or Zonation (Moilanen and Kujala, 2008),

Table 6 Percent of the total budget (US\$100 million) allocated to the 30 ecoactions that receive investment over both 5 and 20 years

to help find good solutions. These software are also good at finding cost-effective solutions, essentially conducting an ROI analysis that incorporates complementarity. (Although Marxan does find cost-effective solutions, it does not technically maximize ROI because the algorithm does not consider benefits beyond the target amount. The algorithm used in Zonation, however, more closely approximates an ROI optimal solution.) Game *et al.* (2008) describe the use of Marxan to find cost-effective solutions to protecting representative examples of reefs on Australia's Great Barrier Reef that also consider the risk of climate change eliminating the expected conservation return after investment. The results illustrate a relationship between cost and probabilistic risk in which a number of reefs that represented very low climate change risk

were not prioritized when conservation budgets were limited because they were valuable to the fishing industry and therefore expensive to convert to protected areas. Instead, limited conservation resources were better spent acquiring a higher number of reefs that were medium to high risk, given the low probability that all will be lost.

ROI Where Costs Are Unknown

All the examples just described depend on knowing the expected investment or cost associated with each alternative being considered. These data, or surrogates for them, cannot always be reliably estimated. This is often the case with

Figure 7 Comparison of the relative performance of ROI analysis recognizing the dependency between actions and their returns. Reproduced from Evans MC, Possingham HP, and Wilson KA (2011) What to do in the face of multiple threats? Incorporating dependencies within a return on investment framework for conservation. *Diversity and Distributions* 17: 437–450, with permission from Wiley.

community-based protected-area initiatives, where the investment cost is largely born by the community that is sacrificing some of its land or sea and numerous cultural, social, economic, and geographic factors influence its willingness to convert part of the customary land or sea to conservation.

Game *et al.* (2011) describe a prioritization process used by The Nature Conservancy and partners in Choiseul Province, Solomon Islands, to help establish a representative network of community-based protected areas. When a community expresses an interest in establishing a protected area, it is presented with a map of the conservation return across its lands and seas. The community is then asked to choose the piece of land or sea with the highest conservation return where it is willing to establish a protected area. After each decision, the map of conservation return for the whole province is updated to consider complementarity with the current set of protected areas. In this way, each decision obtains the highest ROI possible for that decision without having *a priori* knowledge of the investment side of the equation. This is fundamentally equivalent to an ROI approach to conservation prioritization.

Opposition and Challenges

Despite their compelling intention (more conservation for our dollars) and wide array of potential prioritization applications, ROI methods face a series of cultural and philosophical challenges in conservation. General philosophical opposition exists to all prioritization schemes that weigh benefit, cost and probability of success, based on the belief that everything has value and prioritizing means sanctioning the loss of some pieces (e.g., Jachowski and Kesler, 2009). There is also a belief that prioritization schemes

are unable to be responsive to opportunities that are the real driver of conservation actions and therefore unreasonably limit flexibility or are not useful. Neither argument is logically sound (for discussion see Bottrill *et al.*, 2009; Game *et al.*, 2011).

There is also a deeper philosophical distaste for the application of financially driven, business-like approaches to biodiversity conservation (a field that undeniably draws great strength from the beliefs and value systems of those involved and has a far more complicated and existential value system than is present in most businesses). This is a legitimate argument, especially given the clear failure of conventional economic systems during the 2008 global financial crisis. This fundamental debate remains challenging, productive, and relatively unexplored philosophical ground.

ROI methods for conservation also face resistance for a number of more pragmatic reasons. In transferring these approaches from theory to practice, it has been difficult to define return functions that convincingly reflect what people care about. People's belief in the conservation value of a place or strategy are composed of many variables that are not necessarily consistently applied, which makes replicating this in a model extremely difficult. Similarly, the available cost data are often either not robust enough or not considered relevant enough to the decisions at hand (even when the consideration of cost is recognized as critical). A study looking at fine-scale conservation-management costs found them to be poorly correlated with commonly used proxies such as the agricultural value of land (Armsworth *et al.*, 2010). Essentially, it is challenging to capture the nuances of conservation value and opportunity in single-return and investment functions. This challenge has frequently resulted in prioritizations that are biased and opaque but that validate existing beliefs about conservation priority.

Not unique to ROI prioritizations, there is also a technical barrier to its successful implementation. Even the relatively modest mathematical familiarity required for the analyses described here are beyond the expertise of many conservation planners. Consequently, the problem-formulation and optimization methods, although rigorous, are often less trusted (the black-box syndrome) than straightforward approaches that suffer serious methodological deficits (such as ranking and additively combining different variables). However, these same challenges were faced by other systematic decision-support methods such as minimum-set reserve design algorithms (e.g., Marxan) that are now considered standard practice and used around the world by conservation practitioners with widely divergent training. Despite these challenges, current trends in both conservation culture and research suggest that ROI analysis will play an increasing role in future determinations of conservation priority.

Impact of Ecological Restoration on Ecosystem Services

Holly P Jones, University of California, Santa Cruz, CA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Active restoration Actively assisting a system in recovery beyond removing the disturbance.

Ecosystem engineers Species that modify, maintain, or create habitats and modify resource supplies through either their physical structure or by transforming living materials from one state to another.

Ecosystem services Those products or services that nature provides society.

Keystone species Species that have a disproportionate effect on ecosystems relative to their biomass.

Nonuse ecosystem services Benefits which are derived from ecosystems without using them (e.g., existence values – the benefit we derive from knowing something exists).

Novel ecosystems Systems that have conditions and combinations of organisms never seen in the historical past.

Passive recovery Allowing a system to recover on its own without intervention beyond removing the disturbance.

Restoration The process of assisting in the recovery of damaged, degraded, or destroyed ecosystems.

Ecological Restoration

As resource use and human populations grow (Haberl *et al.*, 2004; United Nations, 2004), restoration of degraded ecosystems is becoming one of the most important tools in conservation managers' toolboxes (Dobson *et al.*, 1997; Kareiva *et al.*, 2007). Restoration is critical not only to maintain habitat for biodiversity, but also to provide the ecosystem services necessary for human survival (Dobson *et al.*, 1997; Hobbs and Harris, 2001; Foley *et al.*, 2005; MEA (Millennium Ecosystem Assessment), 2005; Kareiva *et al.*, 2007; Benayas *et al.*, 2009). However, restoration can be costly, complex, and labor-intensive and is not always successful, which has traditionally led to reluctance in pursuing large-scale restoration projects (Hobbs and Harris, 2001; Kumar, 2004; van Andel and Aronson, 2006; Jentsch, 2007). If restoration is to succeed in the context of limited funding and capacity, calculating the value of restoration projects is absolutely critical. As our ability to value ecosystem services continues to develop, the return on investment of restoration projects increasingly looks favorable, even for large-scale restoration projects (TEEB, 2010). This article will discuss the concepts of ecological restoration, ecosystem services, and how they are being merged to show society what it stands to gain from restoring earth's damaged ecosystems.

What is Ecological Restoration?

Ecological restoration has been in practice for centuries. For example, Native Americans in the Washington Cascades lit periodic forest fires to sustain natural ecosystem services, such as food crops and game animal forage (Everett *et al.*, 2000). Despite centuries of restoration projects, restoration ecology was not formally recognized as its own scientific discipline until the 1990s (Allen *et al.*, 1997). Until then, grass-roots restoration projects were common throughout the world in the form of invasive species removal (Howald *et al.*, 2007), native species introductions (Towns and Ferreira, 2001), and

native plant revegetation (D'Antonio *et al.*, 1992). However, most of these projects did not have a common theoretical framework and consisted of a hodgepodge of strategies, goals, successes, and failures (Hobbs and Norton, 1996).

Starting in the 1990s, this incoherence began to change (Hobbs and Norton, 1996; Allen *et al.*, 1997). The National Science Foundation began to expressly request proposals for restoration ecology, and scientists began devising a theoretical framework from which to practice restoration. Current restoration ecology is not like that of the past, because it is now based around sound ecological principals and it uses theoretical frameworks to design experiments. That said, it is still developing and has much progress ahead of it. In fact, the first textbook for use in classroom teachings was only recently published (van Andel and Aronson, 2006).

The Society for Ecological Restoration defines ecological restoration as the process of assisting the recovery of damaged, degraded, or destroyed ecosystems (SER, 2002). This can include removing the original cause of damage and allowing the system to recover on its own (passive recovery), or actively assisting the system in recovery (active restoration). It is important to distinguish passive recovery and active restoration because each has much different costs, capacity needs, and methodology. If systems can recover passively after the agent of damage has been removed, less money, staff, and commitment will be necessary to repair that system. However, ecosystems that need active restoration to recover will require much more time, money, and effort.

Restoration ecologists have begun to design a framework from which to plan restoration projects to remedy the ubiquitous restoration projects built with little ecological knowledge and oftentimes unclear or unattainable restoration goals. It is now widely accepted that the first step of a restoration project is to define the goals of the project clearly. Project goals of "restoring native vegetation" or "recovering a pre-perturbation state" are unacceptable; rather, specific goals of restoring species from X to Y abundance or recovering 85% of natural floodplains on a particular watershed are strived for. The second requirement for a restoration goal is that it should

be realistic. With the belief that ecosystems are dynamic entities (Pickett and Parker, 1994), restoration ecologists realize that restoring something to a state in the past may not be possible, and rather, the goal should focus on societal expectations for the future (van Andel and Aronson, 2006). The third requirement of a restoration goal is that progress toward the goal should be measured explicitly.

One thing that distinguishes restoration ecology from most other hard sciences is its explicit inclusion of societal values in its goals. People set restoration goals, meaning goals are often selected according to subjective views of what society needs or wants from a particular ecosystem. The use of the terms like “ecosystem health” and “ecosystem integrity,” as definitions for restored systems have been particularly controversial. Ecosystem health is defined as “the state or condition of an ecosystem in which its dynamic attributes are expressed within the normal ranges of activity relative to its ecological state of development” (van Andel and Aronson, 2006), while ecosystem integrity is “the state or condition of an ecosystem that displays the biodiversity characteristic of the reference, such as species composition and community structure, and is fully capable of sustaining normal ecosystem functioning” (SER, 2002). Both definitions take the concepts of ecosystem perturbation, resistance, and resilience and add an aspect of societal expectations (van Andel and Aronson, 2006). Integrating society into ecological terms outrages some ecologists (Lancaster, 2000; Davis and Slobodkin, 2004), but restoration ecology, unlike conventional sciences, aims to explicitly incorporate societal expectations into restoration programs. One promising way of incorporating society into restoration goals is using ecosystem services to calculate the value of restoring nature to meet human needs.

Restoration Targets

One significant issue for restoration ecology is the definition of a pre-perturbation state, which, unless resolved, can leave enduring confusion and ambiguous restoration targets. Some restoration ecologists have argued against the use of historical reference data to attain restoration goals for several reasons. First, any attempt to restore systems perturbed by human activity must address the question of how far back in history to go (Diamond, 1987; Hobbs, 2005). In addition, historical and paleontological records are often lacking or incomplete. Finally, using historical reference sites may be very difficult or just impossible because under climate change, shifts of carbon cycles, climate regimes, sea level, and climatic events will change the biophysical make-up of ecosystems to make historical systems difficult or impossible to recreate (Hobbs *et al.*, 2006).

Many restoration projects have moved away from the idea of restoring back to “natural” or prehuman ecosystems, and instead, use existing reference systems that have not been exposed to the perturbation (contemporaneous reference sites) as restoration targets (Harris and Diggelen, 2006). The advantages of modern reference systems are that they reflect contemporary climate regimes, have shown resilience to human activity, and have properties that can be explicitly measured to evaluate restoration progress. Another possible

target for restoration is the functional target (Harris and Diggelen, 2006). This is the idea of using ecosystem function parameters such as primary productivity, energy flow, and perturbation regime as restoration targets. However, these properties cannot be easily manipulated and thus make difficult goals to achieve without considering what community type would approach these targets. Finally, some projects aim to restore a suite of ecosystem services to society (Harris and Diggelen, 2006). Using ecosystem service targets can help managers gain society’s support for restoration by detailing the benefits of restoration in a currency that everyone understands.

Restoring Entire Ecosystems, a Few Ecosystem Drivers, or Ecosystem Services

There has been significant debate over whether to restore entire ecosystems or just a few ecosystem drivers (Goldstein, 1999; Risser, 1999; Walker, 1999), and it is complicated by divergent views about the nature of communities and ecosystems. Ecosystems can be viewed as stocks and flows of their biotic and abiotic components, which is an entire ecosystem view (Odum, 1969). An alternative view is that ecosystems are composed of communities of species pitted against one another in outright Darwinian evolutionary struggles, and only a few of these influence the entire community, which is an ecosystem driver view (Oksanen, 1988). Both perspectives have advantages and disadvantages for restoration ecology. A restoration project that focuses on ecosystem drivers emphasizes key components of ecosystems, may enhance biodiversity, and can require less time and cost to carry out than whole-ecosystem restorations. However, this focus on single species or small groups of species fails to recognize the importance of processes at the landscape scale, assumes untested links between components of communities, may inadvertently damage species not targeted in restoration, and may divert attention from other important species (Ehrenfeld, 2000).

The ecosystem view, however, recognizes the importance of landscape-scale processes to species persistence, incorporates the view that systems are dynamic, and can help to encourage participation from a variety of agencies and stakeholders. However, attempting to restore entire ecosystems is complicated because ecosystem functions are difficult to define or measure. Even with adequate definitions, functions sometimes do not correlate with each other and often operate on different temporal and spatial scales. This makes realistic restoration goals difficult to set.

The third concept is the ecosystem services view (Ehrenfeld, 2000). Projects with goals of restoring ecosystem services have clearly identified goals and tend to generate public support and funding. However, such projects may have difficult-to-measure services, are contingent upon willingness-to-pay, must overcome trade-offs between equally desirable ecosystem services, and could be compromised if changes in society, technology, or the economy devalue the services that such projects are targeting. Ecosystem services are difficult to distinguish from the ecosystem view because restoring ecosystem services requires restoring the same ecosystem functions that are the targets of whole-ecosystem restoration projects. As such, the ecosystem service viewpoint can be seen as a strategy

to justify restoration rather than a completely different viewpoint.

Each of these views for setting restoration goals has advantages and disadvantages. No one paradigm is correct for restoration – instead, each one should be considered in turn before deciding which paradigm is appropriate for the focal restoration project. In many cases, more than one paradigm will apply. For example, restoring an entire watershed must focus on landscape-scale processes such as hydrologic flows, river diversions, and runoff control. Ecosystem driver restoration goals are unrealistic in this case because its scope is well beyond restoring one or a few species. However, whole-ecosystem goals and ecosystem service goals are both appropriate. Whole-ecosystem frameworks can be used to help define the restoration targets, while ecosystem services can be used to help generate public support for the project. Attempting to create universally applicable laws may not be necessary for restoration as it is such a broad, diverse, and complex discipline (Ehrenfeld, 2000). Instead, using common sense principles to decide which framework works for each unique situation will ensure each restoration project has a better chance of reaching the goals that are appropriate in each context. Below are examples of projects that use each framework as the basis for setting restoration goals.

Restoration of Ecosystem Drivers

Some ecosystems seem to be largely driven by one or a few species, in terms of ecosystem structure or function. Keystone species are one example of ecosystem-driving species and they are so named because they are akin to a keystone that supports an entire arch – without the keystone, the entire arch would collapse (Paine, 1995). Keystone species have a disproportionate effect on ecosystems relative to their biomass and when they are affected or removed by a perturbation, the effects on ecosystems can be tremendous (Paine, 1966). Sea otters are a classic example of a keystone species in ocean kelp forests. Otters prefer to consume herbivorous invertebrates such as sea urchins, which are particularly voracious consumers of kelp. When otters are removed from the system (which occurred extensively along the west coast of North America in the 1800s due to otter hunting for pelts), invertebrate populations explode and quickly consume and destroy the kelp forests, which results in the collapse of an entire system – without the kelp, fish and invertebrate species lose their habitat, and abiotic conditions (light, nutrient availability) fundamentally change (Estes and Duggins, 1995). Kelp forests that have been destroyed by uncontrolled herbivorous invertebrates have been termed urchin barrens because all that is left are large populations of urchins. In this way, the loss or reduction of a single species can result in devastating losses to ecosystem services including opportunities for recreation, commercial fishing nursery grounds, and carbon sequestration.

Other species thought to be the key drivers of ecosystem structure or function are termed ecosystem engineers. These species modify, maintain, or create habitats and modify resource supplies through either their physical structure (e.g., trees in forests), or by their transforming living materials from one state to another (e.g., beavers building dams; Jones *et al.*, 1994). Coral reefs are classic examples of ecosystem engineers.

Their structure changes the coastal environment and modifies the abundance and distribution of resources (e.g., light, nutrient availability), and protects entire reef systems and coastal ecosystems from water force and wave action (Anderson, 1992; Moberg and Rönnbäck, 2003). This makes perturbations to corals especially dramatic because they alter entire ecosystems as opposed to just one species. Loss of corals reduces the ecosystem services that corals provide – commercially important fish and invertebrate species lose their habitat, coastal communities are less protected from storm surges and wave action, and recreational and tourist opportunities are diminished.

Restoring systems that have lost their keystone species or ecosystem engineers usually consists of restoring the species to its historical location. For example, over the past century, riparian ecosystems in much of the western US have been lost from large-scale recruitment failures of key riparian tree species like native cottonwoods and aspens. Mounting evidence has suggested that these failures were due to the system losing its top predators – wolves – from human hunting pressures in the 1920s (Vander Zanden *et al.*, 2006). The loss of wolves led elk to change their foraging behavior and forage for cottonwoods and aspens without fear of predation from wolves (Ripple *et al.*, 2001; Beschta, 2003). Wolves were reintroduced in the mid-1990s and their regulation of elk populations and foraging behavior has allowed riparian vegetation to recover. This recovery is expected to improve bird nesting habitat, stabilize stream banks, strengthen ecosystem linkages, and moderate water temperatures (Osborne and Kovacic, 1993; Berger *et al.*, 2001). In this case, reestablishment of one keystone species has carried over to the entire ecosystem. It illustrates the relative simplicity of restoring systems that have lost only one of their key species.

Whole-ecosystem Restoration

Restoring entire ecosystems is an ambitious undertaking. Whole-ecosystem restoration involves repairing or restoring most if not all of the functions of an ecosystem following a perturbation. It most often refers to restoration projects at the landscape scale and is arguably one of the most efficient ways to bolster ecosystem services because restoring such large-scale processes results in provisioning of a wealth of ecosystem services at vast scales. For example, efforts to restore the Mississippi–Ohio–Missouri river basin following eutrophication from farm runoff is projected to reduce hypoxia in the Gulf of Mexico, improve water quality for commercially important fish and invertebrate species, provide large swaths of riparian floodplains to help regulate floodwaters for people and croplands, improve water quality and quantity for local residents, and provide habitat for local wildlife (Mitsch and Day, 2006). This single restoration action, carried out by various organizations and covering multiple states, and millions of hectares, has the potential for a much larger ecosystem service benefit than smaller-scale restorations aimed at one or a few species or habitats. It is also significantly more complex because it covers more habitats, ecosystem processes, species, and jurisdictions than smaller-scale restorations. As such, it is a good illustration of both the immense benefits and challenges of attempting to restore entire ecosystems.

Ecosystem Service Restoration

Since the seminal works defining ecosystem services – also known as natural capital (Daily, 1997) – and valuing them (Costanza *et al.*, 1997), restoration ecology has been increasingly focused on restoring not just species or ecosystems, but also ecosystem service values. Ecosystem services are increasingly called for as a means to justify restoration, set goals that are more realistic than historical targets given continuing climate and global change, and to illustrate the connection between people and nature (Cairns, 2000; Hobbs and Cramer, 2008; Chazdon *et al.*, 2009; Jackson and Hobbs, 2009). Ecosystem services are those products or services that nature provides society. There are many different ways to categorize ecosystem services, but most are blocked into four main types (MEA, 2005): provisioning – those that provide a product such as croplands provide food; regulating – those that provide regulation of function such as coastal wetlands provide wave attenuation for coastal populations faced with tropical storms (Alongi, 2008; Das and Vincent, 2009; Shepard *et al.*, 2011); support – those that support other ecosystem services such as primary production; and cultural – those that provide cultural, aesthetic, or spiritual benefits such as national parks provide recreational opportunities. Ecosystem services are covered extensively elsewhere in this volume, so they are discussed only in reference to restoration in this article.

Ecosystems naturally provide some of these benefits whether they are degraded or intact, but intact systems have higher potential for ecosystem services than do degraded ones (Chazdon, 2008; Benayas *et al.*, 2009). This is where ecological restoration and ecosystem services combine – restoration can help ecosystems regain their function and thereby increase the potential for ecosystems to provide services to humankind. Restoring ecosystem services, then, requires restoring the underlying ecosystem functions that relate to the desired services. Each service relies on an underlying ecosystem process for its production. For example, Table 1 lists some common ecosystem services, ecosystems, and what ecosystem process is necessary for each service. As the table illustrates, restoring ecosystem services is no different than restoring key ecosystem functions. Instead, using ecosystem services as a target for restoration is a way to communicate how society will benefit from restoring key ecosystem functions, generate public support, and generate funding mechanisms for restoration projects.

It is still difficult to glean examples of restoration projects whose specific goals were to recover ecosystem services. This stems from issues inherent in defining the functions needed to restore the service, an incomplete understanding of ecosystem dynamics, and from the disconnect between ecological and economic understanding of ecosystem service restoration (Kremen, 2005; Palmer and Filoso, 2009; Wegner and Pascual, 2011). Instead, it is more common to use ecosystem service targets as a call to restore. For example, a model was recently developed for The Drakensberg Mountains of South Africa to calculate the economic benefits of restoring degraded grasslands and riparian zones as ways to increase the low base water flows during the winter months (Mander *et al.*, 2008). The restoration would cost around \$5.1 million over 7 years, while the ecosystem service benefits of additional water, sediment reduction, and carbon sequestration are valued at \$8.4 million per year (Blignaut *et al.*, 2010). The study and many other similar studies (Loomis *et al.*, 2000; Tong *et al.*, 2007; Yu *et al.*, 2009) provide the motivation behind large-scale restoration projects that attempt to align nature with societal goals.

A second way that ecosystem services are incorporated into restoration is through hindsight. Ecosystems throughout the world have been restored, but the concept of ecosystem services is so new that it is more common to calculate the ecosystem service benefits of past restoration projects, or to frame past projects in terms of ecosystem services now that we know how effective ecosystem services can be in gathering public support for restoration (e.g., Aronson *et al.*, 2007). For example, the island-scale ecological restoration on Tiritiri Matangi Island, New Zealand, was conceived as a way to restore native flora and fauna, but the ecosystem service benefits of the restoration project are now being touted as some of the greatest benefits of restoration (Craig and Vesely, 2007). As the practice of restoration catches up with the theory of ecosystem services, we will begin to see many restoration projects with specific goals of restoring ecosystem services.

Other Key Considerations for Ecological Restoration

Novel Ecosystems

The idea that there are novel or synthetic ecosystems – those that have conditions and combinations of organisms never before seen – goes back as far as Odum (1962). Recent work

Table 1 Ten of the most critical ecosystem services for human well-being and the associated ecosystem functions that are critical in providing those services. While ecological restoration can be framed in terms of the ecosystem services restoration provides, it is the underlying ecosystem functions which must be restored to provide those services

Ecosystem service	Corresponding ecosystem processes
Air purification	Plant respiration, photosynthesis, toxin filtration, nutrient filtration, nutrient cycling
Carbon sequestration	Carbon storage, carbon cycling, photosynthesis
Climate regulation	Carbon storage, carbon cycling, photosynthesis, light absorption, light reflection, evaporation, transpiration
Coastal defense from storms, sea-level rise	Wave attenuation, water absorption, water retention, water storage, land stabilization
Crop pollination	Pollinator population dynamics
Fertile soils	Nutrient cycling, nutrient mineralization, water absorption, water retention, nutrient fixing
Flood protection	Floodwater absorption, floodwater retention, wave attenuation, water storage
Freshwater provisioning	Water absorption, water retention, water storage
Timber	Forest net primary production, photosynthesis
Water purification	Nutrient filtration, toxin filtration, nutrient retention/cycling, water storage

has termed such systems novel ecosystems (also known as “emerging” or “no-analog” systems) and has defined them as those “containing new combinations of species that arise through human action, environmental change, and the impacts of the deliberate and inadvertent introduction of species from other parts of the world” (Hobbs *et al.*, 2009; Marris, 2011). Novel ecosystems are an ambiguous concept because depending on the timeframe of interest, anything could be considered novel. However, the main proponents of using novel ecosystems to help guide restoration efforts suggest that the accelerated pace and breakdown of biogeographic barriers sets current novel ecosystems apart from the past in terms of the increased rate of novel environment appearance, novel species combinations, and altered ecosystem functioning (Hobbs *et al.*, 2009). The utility of terming systems novel seems to move restoration targets away from historical states and instead argues for ecosystem service and ecosystem function restoration goals (Jackson and Hobbs, 2009). This is laudable but much of the debate on using historical reference sites has already been settled and so the introduction of this new terminology is still somewhat puzzling.

Novel ecosystems have arbitrary definitions and could therefore represent a range of scenarios from a severely perturbed system to one that has been completely replaced by new species. Another component of the novel system framework is the hybrid ecosystem, which also has an arbitrary definition – somewhere between a novel and an historical system – and cannot be clearly distinguished from just perturbed or novel ecosystems. Indeed, a large perturbation such as logging can result in a complete replacement of the previous vegetation with new, early-successional and possibly invasive grasses. Is this then a novel ecosystem because it is different from the historical past and likely made up of new species combinations? Or is it merely a perturbed system in the beginning stages of recovery? Their arbitrary definitions make novel systems impossible to distinguish from just severely perturbed systems and therefore cause difficulty in identifying the extent of their existence, illustrating their impact, and using them as potential restoration targets. Despite these difficulties, the existence of novel ecosystems is certainly another good argument against using historical references in restoration, but focusing our energy on ambiguously defined and difficult-to-identify ecosystems could also take away from sorely needed advancements in using ecosystem services to calculate return on restoration investments.

Restoration and Global Change

It is important to recognize that ecosystem repair from various perturbations is happening against a backdrop of global change that has accelerated at unprecedented rates since the industrial revolution (Baines and Folland, 2007; IPCC, 2007; Maslanik *et al.*, 2007; Belkin, 2009; Gregory *et al.*, 2009). From sea-level rise to heightened hurricane activity, longer and more frequent droughts and floods, and acidification of the world’s oceans, ecosystems are undergoing rapid change (Allison *et al.*, 2009; Fussler, 2009). This presents an interesting conundrum: How do we choose restoration targets when much of the world’s ecosystem processes are in a state of flux and are likely to continue changing for the foreseeable future? This dynamic and unpredictable climate argues against the use of historical

baselines for restoration because they will be increasingly impossible to recreate amidst changing biophysical conditions (Harris *et al.*, 2006). Indeed, many have suggested that restoration of processes, rather than historical conditions, will give restoration the best chances of success in a changing world (Harris *et al.*, 2006). In a changing world, our restoration goals are likely to include ecosystems that were never before seen in historical times because we are predicted to experience climate shifts never before realized in such a short time span. The interaction between ecological restoration and global change is an understudied area that will be of rapidly growing interest as we watch systems change before our eyes.

Climate change also presents an interesting challenge to legislation that protects critical habitat for species of concern like the Endangered Species Act. Changing ecosystem processes may mean that critical habitats will shift according to species’ biophysical envelopes, and so, protected habitats will no longer be suitable for the species the protection was created for (Harris *et al.*, 2006). Restoration may provide a critical answer to protecting these species – it may be necessary to restore habitats and create shelter for species that will need to migrate given climate change (Harris *et al.*, 2006).

Ecological Restoration and Ecosystem Services

Ecosystem Restoration Potential

Human population now exceeds seven billion people and this number is projected to grow to eight billion by 2050 (United Nations, 2004). As our population grows, so too do our technological demands, thirst for resources, and exploitation of nature to meet our expanding needs. We have fundamentally altered most ecosystem processes, leaving few areas on Earth untouched by people in some way (Kareiva and Marvier, 2011). Humans have been domesticating nature to meet our needs for centuries (Kareiva *et al.*, 2007), but the rate of ecosystem alteration has spiked since the industrial revolution. As we continue to use nature’s capital to meet our needs, we also threaten to destroy the very resources that we depend on for survival. We have transformed around half of Earth’s surface area to grazing or croplands (MEA, 2005). More than 50% of the world’s forests have been lost through this extreme transformation (MEA, 2005). Although providing food for the masses is a necessary service that ecosystems provide, it is often done at the expense of other ecosystem services such as water quality and quantity regulation, climate regulation, and carbon sequestration. Our insatiable thirst for resources and to control nature has driven the largest mammals on each continent to extinction or severe depletion, fundamentally altering food webs across the globe (Woodroffe, 2000; Lyons *et al.*, 2004). No marine ecosystem on earth is untouched by people and almost half of the world’s oceans face multiple threats (Halpern *et al.*, 2008). As such, there is substantial concern that we are leaving a legacy of extinction, biodiversity loss, and unsustainable exploitation of nature to future generations.

Humans are arguably better off now than in previous generations. We are able to feed the masses, control predators, alter natural disturbance regimes, and build infrastructure to help

protect us from storms. So what has our domination over nature done to the world's natural capital? The answer is complex because there are trade-offs between different ecosystem services (Kareiva *et al.*, 2007). For example, food provisioning is a service that nature provides but as we replace ecosystems with cropland, other ecosystem services are diminished. Maximizing crop production requires the input of artificial fertilizer, which has caused massive nutrient leaching into waterways and has led to eutrophication of rivers, lakes, estuaries, and oceans. This has led to toxic algal blooms and has created dead zones around the world (Galloway *et al.*, 2003). Similarly, we rely on timber for our furniture, shelter, paper, and other household products. But logging and deforestation has caused soil erosion, which reduces forests' capacity to absorb floodwaters, reduces water quality, and can alter climate regulation (Daily, 1997; Sweeney *et al.*, 2004; Dobson *et al.*, 2006). We use fossil fuels to travel, heat our homes, produce food, and access water and electricity, but the by-products of this energy demand are increased greenhouse gases and shifting climate regimes that ultimately threaten our very existence (IPCC, 2007). Our marine fisheries and coastal development have depleted 91% of ecologically and economically important coastal marine species to less than 50% of their historical abundances (Worm *et al.*, 2006) and destroyed more than 50% of the world's mangroves (World Resources Institute, 1996). This severe biodiversity depletion has led to a 33% reduction of fish stocks, a 69% reduction in nursery habitat for marine organisms, and a 63% reduction in water filtration ecosystem services (Worm *et al.*, 2006). So while we have done generally well at taming nature to meet our needs, it has come at a price to ecosystems and the other important services they provide. This price threatens to impact our livelihoods, standard of living, ability to withstand environmental perturbations, and at the most basic level, our persistence. All of these threats may not be realized in our lifetime, but they are very real consequences that will be passed on to future generations.

At the same time, there is cause for some optimism. Ecological restoration of ecosystem services offers great promise for restoring the balance between society and nature and to pass on a more hopeful legacy to future generations. As E.O. Wilson so eloquently put it, "Here is the means to end the great extinction spasm. The next century will, I believe, be the era of restoration in ecology." Combining ecological restoration with ecosystem services can be challenging because they are both such nascent disciplines, there are many trade-offs to study and account for, and the two disciplines (restoration and economics) have so often been at odds with each other in the past. However, the imperative is clear: No place on Earth is untouched by people and so restoring ecosystem services to ensure our future survival will be a key focus of ecological restoration moving forward (Kareiva and Marvier, 2011). Restoring ecosystem services will be one of the most efficient ways to repair ecosystems and ensure human prosperity together in one action.

Bolstering Ecosystem Services as a By-Product of Restoration

Many restoration projects that address ecosystem services view them as a co-benefit of restoration rather than a goal of restoration. This is because restoration was historically justified

as a moral imperative (Leopold, 1949). With the realization that moral arguments are not as effective as economic ones, restoration ecologists have increasingly looked at past restoration projects to show how they have benefited society. One of the most comprehensive studies to date illustrating the effects of ecosystem restoration on ecosystem services was a meta-analysis that compared ecosystem services for degraded, restored, and unperturbed reference ecosystems (Benayas *et al.*, 2009). The study showed that restoration increased ecosystem services by 125% relative to degraded systems, giving much hope for restoration to play a key role in repairing nature's capital. However, ecosystem services were still lower in restored systems versus unperturbed systems, indicating conservation of unperturbed systems will continue to be an important strategy for maintaining ecosystem services.

Many other studies illustrate what society stands to gain from ecological restoration in myriad ecosystems across multiple scales. Establishing marine protected areas to help fish populations recover from exploitation leads to increased fish biomass, more catch per unit effort for fisheries, and increased tourism opportunities (Worm *et al.*, 2006), which provides hope that passive restoration can be an effective tool to repair ocean fisheries while simultaneously providing cultural ecosystem services. Mangrove reforestation around Bangladesh has increased fishery potential, provided 600,000 m³ in forest products, bolstered livelihoods, and stabilized coastal land (Moberg and Rönnbäck, 2003). The US Mississippi Delta provides \$12–47 billion per year in flood and hurricane protection, water supply, water quality, recreation, and fishery ecosystem services (Batker *et al.*, 2010). Moreover, if levees along the Delta were replaced with restored wetlands, there would be an estimated net gain of \$62 billion in ecosystem services annually (Batker *et al.*, 2010). Each of these studies illustrates the enormous potential for ecosystem service restoration in diverse ecosystems throughout the globe.

Using Ecosystem Services as Justification for Restoration

One of the biggest utilities of ecosystem services in ecological restoration is as a justification to carry out restoration projects. In a resource and capacity-limited society, it is increasingly important that restoration projects make the case to society on their worth. Monetary justification is in sharp contrast to the moral justifications Aldo Leopold so vividly articulated in his *Land Ethic* (Leopold, 1949). While Leopold might disagree with the means, he would undoubtedly approve of the outcome of using ecosystem services to justify restoration because it shows society how connected to nature people are and speaks to society in a currency that everyone understands and appreciates. This is a modern way to help people understand their dependence on nature and bring even those living in industrialized cities (who use the majority of ecosystem services) a little bit closer to the land.

The overwhelming majority of projects that interweave restoration with ecosystem services are in the developing stages and use ecosystem services to calculate the projected benefits of the proposed restoration (e.g., Loomis *et al.*, 2000; Tong *et al.*, 2007; Yu *et al.*, 2009; Batker *et al.*, 2010). For example, one study was done on the benefits of restoring the historical

floodplains along the lower Danube River in Europe. Historical floodplains were converted to dykes for agriculture, aquaculture, and forestry, which reduced the capacity of the floodplain to absorb floodwaters and has increased flood peaks and spurred interest in restoration. The study showed that restored floodplains would provide \$700 per hectare in flood control, provision of fish, forestry, and animal fodder, nutrient retention, and recreational benefits. In this case, projected ecosystem service benefits were two-fold higher than the cost of restoring this huge swath of land, which makes a strong case for investing in restoration (Ebert *et al.*, 2009). Another study valued coastal wetlands for a single ecosystem service – storm protection – over the entire US. The authors determined wetland value by calculating the amount of storm damage in places with varying degrees of wetland protection and found that a loss of just one hectare of wetlands cost on average \$33,000 dollars in hurricane damage. US wetlands currently provide \$23.2 billion annually in storm protection and while no restoration costs were calculated, the study concludes that restoring wetlands is an extremely cost-effective strategy (Costanza *et al.*, 2008). This massive ecosystem service value of coastal wetlands would be even higher if additional ecosystem services such as water filtration, toxin filtration, carbon sequestration, nursery habitat for commercially important fish, and recreational and tourism opportunities were included. This underscores the massive potential for large-scale restoration efforts to provide society with tangible benefits and preserve biodiversity in a single action.

Using Ecosystem Services as Explicit Restoration Targets

Billions of dollars are spent annually restoring ecosystems (Enserink, 1999; Zhang *et al.*, 2000), but with little to no consideration of the ecosystem service returns on the restoration investments (but see Goldstein *et al.*, 2008). With so much money invested into restoring ecosystems, it is puzzling that so few restoration actions are prioritized according to the ecosystem services they can provide. As these two rapidly emerging fields continue to develop and expand, there will undoubtedly be growing numbers of restoration projects with specific ecosystem service goals, or projects that are prioritized by the amount of services they are likely to produce. Most restoration projects have a whole suite of ecosystem service benefits (Benayas *et al.*, 2009). However, a key area for theoretical advancement is looking at the trade-offs between ecosystem services that specific restoration actions would entail. For example, reforesting an area that has been used as cropland will take away the food provisioning that the crops provide but may reinstate key water purification, flood protection, and carbon sequestration services. Studying these synergies and how they interact to restore ecosystems and contribute to human well-being will likely be one of the cutting-edge applications of ecosystem service restoration in the future.

The Future of Restoration and Ecosystem Services

Tackling the Biodiversity Crisis

Opinions differ on how best to stem the enormous biodiversity crisis that we face. The traditional conservation

approach has been to preserve “natural” ecosystems by excluding people (Mittermeier *et al.*, 1998; Reid, 1998; Holl and Aide, 2011). Inherent in this approach is the idea that people and ecosystems are separate entities – that humans are not part of nature. The growing consensus is that this viewpoint is antiquated, often produces maladapted conservation outcomes that may be difficult to maintain in perpetuity, and encourages conservation of nature at the expense of people (McNeely, 1994; Holling, 1996; Berkes, 2004; Kareiva and Marvier, 2011). While conserving biodiversity will continue to be an important strategy moving forward, doing so at the expense of people may ostracize man from nature and hinder conservation objectives. Restoring the earth’s damaged ecosystem services is one way to entwine two important objectives: Protecting and preserving biodiversity and providing the necessary functions and services for human survival. This is a unique way to reconnect people with nature and to simultaneously justify the need for restoring the damage we have inflicted. This is a relatively new way to engage society into conservation objectives and it has much progress ahead of it to ensure that it continues to be an effective conservation strategy.

Even so, this is an exciting time to be a restoration ecologist. Restoration ecology is and will continue to be one of the most important sciences of the twenty-first century because of the widespread need to repair ecosystems globally. Society has placed great hopes on the ability of restoration to repair Earth’s damaged ecosystems and ensure continued survival for future generations (Palmer and Filoso, 2009). This is enormous pressure for such a nascent science but we are equal to the challenge. As restoration ecology continues to incorporate ecosystem services into its frameworks, there are important areas of research that will help to ensure that restoration is operational as a science but also meets society’s needs.

Key Challenges

Many studies calculate ecosystem service benefits of conservation, restoration, or management projects. But very few of these examples examine the trade-offs and synergies of different ecosystem service benefits and so it remains difficult to predict how different restoration actions will affect ecosystem services as a whole. To understand these trade-offs, we must gain better understandings of how underlying ecosystem processes change with different restoration options and how ecosystem services change as a result (Palmer and Filoso, 2009). Right now, there are few satisfactory ways to value nonuse ecosystem services such as aesthetic values and so cultural ecosystem services are rarely valued (Portney, 1994; Benayas *et al.*, 2009). Even indirect use (nonmarket) services can be valued in so many different ways (Pearce, 1993) that it becomes difficult to determine the accuracy of different valuation studies without intimate knowledge of economic theory. While this will continue to be a challenge for restoring ecosystem services going forward, it is also a prime opportunity to expand our existing theories and develop them to meet society’s needs.

The interactions between ecological restoration, ecosystem service valuation, and climate change present enormous

opportunities for further research. Discussions on climate change and ecological restoration are mostly theoretical (Harris *et al.*, 2006), so there is ample opportunity for empirical studies to inform the discussion. Relatively more attention has been given to the effects of climate change on ecosystem services (Schroter *et al.*, 2005), but there is still a dearth of studies that combine restoration, climate change, and ecosystem services. For example, it will be important to prioritize restoration efforts that help people adapt to climate change but it is unclear which restoration efforts will have the greatest adaptation benefits to people (Jones *et al.*, 2012). Restoring coastal wetlands may be one of the most efficient and economical ways to protect people from sea-level rise and tropical storms (Costanza *et al.*, 2008), but more research is needed to analyze the costs, benefits, and trade-offs of such restoration programs. Other areas may not be worth investing in restoring if they will be inundated by sea-level rise or destroyed by changing temperature regimes. Some species or ecosystems may not be resilient to projected climate change and therefore may be precluded from restoration investment, and others may thrive under climate change scenarios so they may be sought out as restoration targets. Empirical research is needed to examine different scenarios so that we can best prioritize our restoration actions in a changing world.

Integrating Restoration Goals with Societal Values

Society is at a crossroads. We can continue to exploit Earth's ecosystems with little thought to the effects it might have on other species or even future generations of our own species. We can unsustainably exploit resources and leave a legacy of extinction and degradation to future generations. Or we can recognize that our actions are not without consequence, take responsibility for those consequences, and begin making the difficult decisions that are necessary to ensure that future generations will have access to the food, clean water, timber, shelter, and other ecosystem services we all enjoy. Undoubtedly we have damaged ecosystems globally, but we do have the ability to repair damage, restore ecosystems, and ensure ecosystems can continue to provide the services that we all depend on for survival. This may require a large investment in restoration projects, a commitment to scientific research, and a change in our perception of our relationship with nature. But even in its infancy, restoration of ecosystem services can show society how much we stand to gain by making these changes. Using ecosystem service valuation to justify ecological restoration is just one way to reconnect people with nature and to start making more sustainable choices. In current society, it is also arguably the most salient one – the time to try to convince humanity that it is our moral duty to live in balance with the Earth has passed; it is now time to frame the imperative to restore differently, so that it speaks to everyone rather than a selected few.

Making the economic case for restoration will be challenging going forward – ecosystem service valuation and ecological restoration still have much progress ahead of them. This is daunting because it is difficult to join two constantly changing disciplines, but it is also promising because they can both be developed alongside one another to leave them poised to

address the profound issues that our society faces. Restoration goals must be explicit, achievable, and take into account the varying views of ecosystems, societal expectations, and the dynamic nature of ecosystems. As we increasingly accept that invasive species, climate change, and unprecedented land transformation will produce novel ecosystems and species combinations never before seen, restoration may have to be directed toward some new system as opposed to a historical baseline (Marris, 2011). Restoration ecology is one science where creativity is necessary, along with scientific intellect, to achieve goals. Incorporating ecosystem services into restoration will require even more careful thought, ingenuity, and creativity. As these fields grow and expand, they will continue to push the boundaries of restoration to what might currently seem impossible. This progress will certainly be necessary in the face of an ever-growing human population, constant global change, and continued stress on the ecosystems that we depend on for survival.

Appendix

List of Courses

1. Restoration Ecology
2. Biodiversity Conservation
3. Ecological Economics

Implications of Urbanization for Conservation and Biodiversity Protection

Robert Ian McDonald, The Nature Conservancy, Arlington, VA, USA

© 2013 Elsevier Inc. All rights reserved.

Glossary

Compact city theory The theory that more compact cities, with greater population density, are more efficient, use less energy per capita, and have less environmental impact per capita than less compact cities.

Ecosystem services The positive benefits that humanity obtains from ecological processes.

Sprawl inequality The idea that the majority of habitat loss from urban expansion is due to a minority of new

housing unit creation, typically at the edges of the urban area. Similarly, a minority of households live on parcels that cover the majority of the urban area.

Urbanization Generally, the process of urban growth. Often used more specifically to refer to an increase in the proportion of total population that lives in cities.

Urban sprawl Urban development that occurs at a relatively low population density and/or takes a large amount of land.

Why Think About Cities?

An Urban World

Homo sapiens sapiens is now predominately an urban-dwelling creature. For the first time in human history, a majority (50.4%) of humanity lives in urban areas (Figure 1). By 2050, there will likely be 2.8 billion new urbanites (UNPD, 2009), a dramatic rate of urban population growth that, if it could be compressed to one place on the globe, is the equivalent of building a city the size of San Antonio, Texas, every week (cf. McDonald, 2008). In tens of thousands of cities across the globe, bricks are being laid, concrete is being poured, and new businesses and households are being formed. This article aims to answer a simple question: What are the main implications of this massive urban growth on biodiversity, ecosystem services, and conservation?

Demographic Realities

Urbanization, the increase over time in the proportion of a population that lives in urban areas, is strongly correlated with

economic development and decrease in fertility. This shift is often called the demographic transition. Poor, predominately rural societies have a high fertility rate. As economic development occurs, a greater and greater proportion of the population lives in cities, and various social and economic incentives encourage a shift to smaller family size. It is generally not clear whether economic development causes urbanization or vice versa; the two processes are often inextricably linked (Montgomery *et al.*, 2003).

Note that urban growth, in terms of an increase in the absolute number of people living in a city, is technically different than urbanization. Urban population change, like that of all populations, is the sum of the natural increase (births minus deaths) and net migration (immigration minus emigration). The growth of most cities' population is due to both natural increase and migration, although the relative strength of the two effects varies by society. However, most cities have lower rates of natural increase than rural areas, so if economic development is to increase the proportion of people that live in cities, significant rural-to-urban migration must occur (Montgomery, 2008).

Figure 1 Trends in population over time, by region. Left panel: Total population, both rural and urban, over time. Only Africa and Asia are still substantially increasing. Right panel: Percent of the population in urban areas. Africa and Asia are significantly more rural than other regions. Data from the UNPD (2009) *World Urbanization Prospects: The 2009 Revision*. New York: United Nations Population Division.

From the perspective of an individual in the countryside, why move to the city? There are generally better employment opportunities and better wages (Anas *et al.*, 1998). At present, there is also often better health care in cities, although this has not always been the case – in the nineteenth century, European dwellers were substantially less healthy than those in the countryside, but in developing countries today the converse is true (Mace, 2008). There are generally better educational opportunities in cities, and children have a greater variety of potential occupation to choose from. Collectively, these drivers of urbanization (Seto *et al.*, 2010) are sometimes called “pull” factors, to contrast with factors that occasionally push people from rural areas to cities (e.g., war, famine, and political instability).

Why set up shop in a city from the perspective of a firm? One important reason is that firms gain tangible economic benefits by being near other firms (Seto *et al.*, 2010). These agglomeration economies are one of the fundamental factors driving urban development (Krugman, 1998). For industries that move significant quantities of inputs or outputs, transport costs can be minimized by being near suppliers or customers (von Thünen, 1875). A factory making automobiles, for example, may benefit by being near plants making steel or aluminum.

Another agglomeration economy is the increased ease of communication that comes with proximity. Some sectors, despite not having significant quantities of physical inputs and outputs, tend to cluster (Sassen, 2001). Government and corporate bureaucracies, for example, find communication easier when employers are near one another. Creative endeavors, like film production, often cluster in certain towns because it is cheaper to shoot a film or produce a play if all the necessary staff are in one place (Florida, 2002). Even writing a script or a play is easier when there are other writers around to trade ideas with.

There are also costs that both individuals and firms consider for being in a city. The cost of renting or buying land is significantly higher in a city (McDonald, 2009). There are also negative effects of crowding, such as the productivity lost while workers are stuck in traffic. The rural versus urban split of individuals and firms is ultimately a result of the balance between the positive and negative economic effects of agglomeration in cities. Similarly, within urban areas, where individuals or firms locate is an attempt to balance these same positive and negative effects (Van Ommeren and Rietveld, 2005). As transportation and building technologies change, this economic balance shifts. For instance, highways and new communication technologies like phones and e-mail have made it more profitable for many firms to be at the edges of urban cores, since they have lower costs of doing business but can still gain some benefit from being near a city (Bairoch, 1988).

So far in this discussion one tricky issue has been skipped: How does one define “urban” and “rural?” The ideal definition might vary depending on the issue under study (Montgomery *et al.*, 2003): a researcher studying employment might define cities based on commuting distance to major urban employment centers, while an ecologist studying habitat loss might use a measure of urban land cover. Sometimes political boundaries are used, although in many parts of the world

these do not correspond with the entire metropolitan region. Population density is often used as a definition of urban areas, although population density often varies substantially from an urban core to the suburbs and exurbs of a city. In most metropolitan regions, suburban and exurban land-uses cover the majority of the land area. However, the majority of the population lives at greater density in the core of the city.

What is the Alternative?

To talk sensibly about urbanization and the environment, one has to specify the baseline or counterfactual scenario: What would have happened to the environment without the rural-to-urban migration (McDonald and Marcotullio, 2011)? This involves considering the distribution of population and associated environmental impact, under some baseline scenario. Without migration to cities, there will be less environmental impacts in cities, but more impacts in the countryside. Moreover, less immigration will potentially limit economic development, and potentially result in a larger total population since rural fertility rates are generally higher.

A simple conceptual model may illustrate the environmental effects of more or less rural-to-urban migration over some (relatively short) time period. Assume a simple, two population model, where some number of people live in the countryside, c , and another number of people live in urban areas, u . Assume also that the population growth rate, α , is different in the two locations, with growth rate usually being higher in rural areas. In each time period, some fraction of people, f , in the rural area moves to the urban area. Then, the growth in population from time t in one time step is

$$c_{t+1} = \alpha_c c_t (1 - f)$$

$$u_{t+1} = \alpha_u (u_t + f c_t)$$

Consider an environmental impact, defined here as a flow in one time step, such as the amount of greenhouse gas pollution in one time step. A simple equation for calculating such an Impact is number of People times the Affluence (e.g., energy consumption per capita) times the Technology (e.g., greenhouse gas pollution per unit energy), the so-called $I=PAT$ equation (cf. Dietz and Rosa, 1997). Assume that the A and T terms are different in the two locations, with A usually being higher in urban locations (city dwellers are richer and can consume more) but T often being lower (city dwellers have more efficient technology, and spatial concentration of population often increases efficiency more). Substituting our population equations above, and multiplying out terms:

$$I_{c,t+1} = \alpha_c c_t A_c T_c - f \alpha_c c_t A_c T_c$$

$$I_{u,t+1} = \alpha_u u_t A_u T_u + f \alpha_u c_t A_u T_u$$

In words, the environmental impact in the countryside is reduced by the amount of impact that those who emigrated would have otherwise caused, given the affluence and technology levels in the countryside. Similarly, the environmental impact in the urban area is increased by the amount of impact

that new immigrants cause, given the affluence and technology levels in the city.

Compare two scenarios, one where there is some migration (i.e., f is greater than zero) and one where there is none (i.e., f equals 0). The increase in environmental impact with migration is then:

$$f c_i (\alpha_u A_u T_u - \alpha_c A_c T_c)$$

The first term is just the number of people who migrate, and is generally nonnegative. The term in parentheses can be positive (migration is a net bad for the environment) or negative (migration is a net good for the environment). In words, if the product of A and T (e.g., greenhouse gases emitted per person) for urban dwellers times the urban birth rate is greater than the product of A and T for rural dwellers times the rural birth rate, the migration increases total impact on the environment.

Another way to look at it is that migration increases total impact on the environment when:

$$\frac{\alpha_u}{\alpha_c} \times \frac{A_u}{A_c} \times \frac{T_u}{T_c} > 1$$

The first term is just the ratio of urban-to-rural rate of natural increase, and is generally less than 1. The second term is the ratio of affluence of urban-to-rural areas, and is generally greater than 1. The third term varies greatly depending on the

environmental impact under consideration, and the socioeconomic and technological context. For instance (McDonald, 2008), US city dwellers generally use less energy to heat their homes because of efficiency gains in multiunit buildings, and hence emit less greenhouse gas emissions from this heating (i.e., this term is less than 1).

Despite the theoretical interest in studying the counterfactual case where there is no rural-to-urban migration, there is no clear historical example of a country that has economically developed without urbanization. Are there societies that are wealthy and that are predominately rural? In general, no (Figure 2). Economic development appears strongly correlated with urbanization. The lack of any historical examples makes evaluation of a hypothetical counterfactual scenario difficult.

There have been considerable policy efforts to slow the pace of urbanization. More than 73% of countries have such policies, which the United Nations Population Fund suggests is the evidence of a growing antiurban bias among policymakers (UNFPA, 2007). Most of these policies have had little effect on rates of urban growth. Many countries, for example, have tried to limit urban growth by denying residency permits to migrants, but have usually just succeeded in creating a large pool of undocumented workers. In short, in the real world there is only little that governments can do to stop urbanization, short of overt violence. A large amount of urban growth is coming as poorer countries, particularly in Africa

Figure 2 Correlation between per capita GDP and percent urban over time for the 20 countries with the greatest population in 2005. Each line represents one country from the period 1950 to 2005, with the arrowhead at the year 2005. Per capita GDP is taken from Maddison (2001), and is shown in 1990 International Geary-Khamis US dollars, a method correct for different purchasing powers over time and space. Percent urban is taken from the World Urbanization Prospects database (UNPD, 2009). Countries are abbreviated as: BAN (Bangladesh), BRA (Brazil), CHN (China), COD (Congo Kinshasa), EGY (Egypt), ETH (Ethiopia), FIL (Philippines), GER (Germany), INA (Indonesia), IND (India), IRI (Iran), JPN (Japan), MEX (Mexico), NGR (Nigeria), PAK (Pakistan), RUS (Russian Federation), THA (Thailand), TUR (Turkey), USA (United States), and VIE (Vietnam).

and Asia, urbanize. There is no realistic alternative to this urbanization (McDonald and Marcotullio, 2011).

Effects of Cities on the Environment

Cities affect the environment in a myriad of ways, and cataloging all of them in one article is impossible. In a sense, it is not surprising that the predominant place of human habitation should have such a great effect on the environment. Urbanization has profound effects on the economy, but it is rarely thought of as a “problem.” What is different about urbanization’s effect on biodiversity and ecosystem services?

One key part of the answer is that most facets of the environment are free or undervalued in the economy of most cities (MEA, 2005). The benefits that nature provides people, ecosystem services, are often nonexcludable goods (e.g., it is impossible practically to stop someone from breathing clean air) and nonrival (e.g., my breathing clean air does not reduce the supply of clean air significantly), and thus are undersupplied by the market like most public goods (Kolstad, 2000). Even where an economic value exists (e.g., water from a municipal water supply), political or market failures often leave natural resources undervalued. For all these reasons, the existence of important biodiversity or ecosystem services provision is not fully or adequately incorporated into urban decision-making. There is every reason, therefore, to worry about cities having undesirable impacts on the environment.

Another useful starting point for discussing the impact of cities and the environment is the observation that these impacts operate over a range of scales (McDonald *et al.*, 2009). At one extreme, the direct physical footprint of urban infrastructure fragments natural habitat. At the other extreme, urban forms affect the extent of greenhouse gas emissions, with global implications for climate change. In the subsections that follow, the impacts that span this range of spatial scales are discussed. First, the effect of the cities’ infrastructure footprint on natural habitat is examined. Second, the impacts on ecosystem service provision are discussed. Third, impacts of cities on protected areas are examined. Finally, some of the positive effects of having people in close proximity with protected areas are discussed.

Natural Habitat and Biodiversity

Urban areas are currently around 3–5% of the Earth’s land surface (Schneider *et al.*, 2009), although the actual figure varies significantly depending on the definition of urban and the spatial grain of analysis (Seto *et al.*, 2010). With urban growth, this will likely double (McDonald, 2008), although the future population of cities is difficult to predict (Seto *et al.*, 2010). However, urban areas are preferentially near coasts and on islands, areas with high species richness, which increases the impact of urban areas on biodiversity (Figure 3). Around 10% of terrestrial vertebrates are in ecoregions that are heavily impacted by urbanization (McDonald *et al.*, 2008). Urban-growth impacts are particularly significant in Mediterranean habitat types, where there is a large concentration of cities as well as many restricted-range endemic species.

The amount of land taken up by a city is a function of the population as well as the amount of built-up area per capita (Angel *et al.*, 2005). Poor countries have very compact cities, with <100 m² per person, simply because few people have access to automobiles and must live within walking distance of jobs. Rich countries tend to have more dispersed cities (generally >100 m² per person), especially those with a great deal of land area available for development (e.g., US cities often exceed 400 m² per person). Also important in controlling urban density are transportation policy (greater investment in roads tends to enhance dispersion, while greater investment tends to minimize dispersion) and zoning, which can either encourage or discourage dense settlement among neighborhoods (Jackson, 1985). In US cities, small proportions of neighborhoods (and people) cover the majority of the urban area and arguably have a large ecological impact, a phenomena sometimes called “sprawl inequality” (McDonald *et al.*, 2010).

Apart from a loss in natural area, expansion of cities also fragments natural habitat. One key effect of this fragmentation is the increase in isolation of natural habitat patches, as the average distance between them increases. Increased isolation tends to reduce population and gene flow among patches, and in the limit, may break a large regional population into several discrete subpopulations. Migration, both seasonal and intergenerational, is also restricted. In general, most mobile taxa like birds are less affected by isolation than less mobile taxa like amphibians, although some apparently mobile species have significant aversion to migrate across urban land cover (Saunders *et al.*, 1991).

Another key effect of fragmentation is to increase the amount of habitat that is near a habitat/nonhabitat edge (Murcia, 1995). This causes a systematic alteration of conditions near the edge, affecting the species and processes found there (Fagan *et al.*, 1999). At forest/nonforest edges, for example, temperature is significantly increased at the edge during the growing season due to greater solar insolation. This can increase average temperatures for tens of meters into the forest interior, changing the climate more than movement of hundreds of kilometers distance in latitude (Smithwick *et al.*, 2003). Roads create a particular type of edge, with particular ecological effects (Forman, 2000). Road noise is another commonly studied edge effect, and has been shown to significantly alter when and how bird species sing (Rheindt, 2003). Finally, biotic interactions may change near edges. For instance, many birds’ nests are more parasitized by cowbirds when the nest is near an edge (Lloyd *et al.*, 2005).

Edge effects and the process of urbanization in general, increase the number and extent of nonnative invasive species (e.g., McDonald and Urban, 2006). Indeed, many authors have commented that there is a suite of “cosmopolitan” species that are present in most cities around the world (Kuhn and Klotz, 2006; McKinney, 2006). Meanwhile, the combined effects of habitat loss, increased isolation, and increased edge effects, as well as competition from invasive species, often leads to the loss of “sensitive” species dependent on larger, more natural blocks of habitat. The net result is often termed “biotic homogenization.” Species richness in cities may actually be higher than that in rural areas, depending on the richness of the suite of cosmopolitan species relative to that in

Figure 3 Distribution of urban areas, taken from the Global Rural/Urban Population (GRUMP) of the World database (CIESIN *et al.*, 2004). Note that the GRUMP database defines urban area based on nighttime light imagery, and includes suburban or exurban areas within the urban extent.

natural habitat, but global species richness declines. The flora and fauna of the world's cities thus becomes similar and homogeneous (Pysek *et al.*, 2004; Hobbs *et al.*, 2006; Grimm *et al.*, 2008).

Ecosystem Service Provision

Just as cities impact biodiversity, they also impact a myriad of ecosystem processes in sometimes complex ways (McDonald *et al.*, 2009). For example, fire ignitions tend to increase near urban land uses, increasing the risk of wildfires starting (Matos *et al.*, 2002). However, widespread suppression of fires soon after they start, designed to minimize the risk of damage to property, often decreases the magnitude of fires that do occur. The exact effect on the natural ecosystem varies, but in almost every case proximity to urban areas alters the fire regime. Occasionally, anthropogenic alteration of the fire regime may have unintended consequences, as when fire suppression leads to fuel buildup, increasing the risk of catastrophic fire.

Altered ecosystem processes of course lead to altered ecosystem service provision as well (McDonald and Marcotullio, 2011). An example might be the capacity of the atmosphere and biosphere to absorb atmospheric pollutants or mitigate their effect. Removal of forest cover as cities grow reduces standing carbon stock and decreases carbon sequestration. Without natural land cover, the natural ability of vegetation to moderate temperature swings is lost and the urban heat island

effect (the tendency of cities to be warmer than their surroundings) is magnified (cf. Kalnay and Cai, 2003). In some cases, the loss vegetation also decreases the environment's ability to absorb or filter low-level air pollutants (Escobedo and Nowak, 2009). However, for other low-level air pollutants like VOC, natural vegetation can actually enhance formation of the pollutant, with negative effects to human health (Leung *et al.*).

Another example of an ecosystem service affected by urbanization would be the water quality (Carpenter *et al.*, 1998). Once urbanization passes a certain threshold in a watershed, water quality is significantly degraded. Urbanization, and particularly new construction activities that disturb the soil, increases sedimentation into streams. Excess nutrients, often from sewage or lawn fertilizer, end up running into streams as well. Finally, in hot climates water running into streams after flowing across hot pavement may thermally shock freshwater ecosystems. All of these factors negatively impact freshwater provision for people downstream (McDonald, 2009).

Cities and Protected Areas

Cities of course affect the biota in protected areas (Figure 4), just as they would affect that of any natural habitat, but city/park relationships also pose a few unique challenges to protected area management (McDonald *et al.*, 2009). At a small scale, many urban parks have vegetation damaged by

Figure 4 Maximum spatial scale at which negative and positive effects from urban areas propagate out and have been observed to affect protected areas. Each line represents an average of the reported distances in the literature. Note that the spatial scale is graphed using a logarithmic axis, and varies from local to global. The number of studies in each category is given (total $N=189$). Adapted from McDonald RI, Forman RTT, Kareiva P, Neugarten R, Salzer D, and Fisher J (2009) Urban effects, distance, and protected areas in an urbanizing world. *Landscape and Urban Planning* 93: 63–75.

trampling or are used for illegal activities (Liddle, 1991). At a medium scale, in many developing countries, illegal logging (Yonariza and Webb, 2007) and hunting within protected areas are more problematic near human settlements. At a broader scale (Cinzano *et al.*, 2001), light from human settlements can affect many species' movement, and can detract from people's wilderness experience in a park (Longcore and Rich, 2004). Finally, urban emissions of greenhouse gases will affect essentially all protected areas on Earth through enhanced global warming.

Perversely from the perspective of a conservationist, protected areas also tend to attract development to their edges (McDonald *et al.*, 2007). In developed economies, there is a large literature that uses hedonic analysis to quantify the amenity value of being near a protected area. Increased habitat conversion for new residential development is also observed near the border of protected areas (e.g., Mansfield *et al.*, 2005).

In developing economies, there are some indications that a similar phenomenon is at work, although the paucity of good global data make broad-scale analyses difficult (Joppa *et al.*, 2009). Certainly there are many cases of tourism spending attracting new people near a park to earn a livelihood (Kruger, 2005).

Positive Impacts

After all this litany of negative effects, it is worth remembering that there are positive things about having cities close to protected areas, or natural areas more generally (McDonald, 2009). Parks near cities are of more value for recreation, simply because people can visit them more easily, an issue of some importance given the epidemic of obesity in many developed economies (Earnhart, 2004; Giles-Corti *et al.*, 2005;

Cohen *et al.*, 2006). Natural areas also offer a place for urbanites to experience nature, relax from their hectic lives, and perhaps draw some spiritual solace from the experience. These noble goals were the idea behind the creation of many large urban parks (Rosenzweig and Blackmar, 1998). Moreover, the role that places like Central Park in Manhattan played in connecting urbanites with nature is important, given that the majority of political activism and fundraising for conservation comes from urbanites (Nash, 2001).

Another benefit of cities arguably is the avoidance of a worse environmental impact under the baseline scenario of no rural-to-urban migration. In a world without such migration, billions more people would be in rural areas, increasing impacts there. In some extreme cases, population migrations (either to cities or elsewhere) have led to agricultural land being abandoned and a return to a more natural state. For instance, New England was once >80% cleared for farming, but was largely abandoned when farming in the US shifted elsewhere. The region is now >90% reforested, and many large mammals like moose have returned to the landscape (Foster and Aber, 2004).

Dependence of cities on Biodiversity and Ecosystem Services

Now to turn from the negative to the positive, cities not only impact biodiversity and ecosystem service provision, but they also depend on them for their continued functioning and the well-being of their citizens. As opposed to the impact of cities on the environment, often a negative economic externality, cities' dependence on ecosystem services is often an example of a positive externality. For many ecosystem services that cities depend on, whose value is not fully captured in economic decisions, there are theoretical reasons to assume that those positive externalities are unlikely to be fully supplied by the free market (Kolstad, 2000).

Dependence on Biodiversity

Despite the relative paucity of biodiversity in urban habitats, or at least taxa that are of global rarity, cities are culturally often the center of demand for biodiversity conservation. Urban dwellers are historically advocates for conservation, often more than rural dwellers. Indeed, in the last 50 years, the processes of urbanization and economic development are correlated with the creation of protected areas, one of the principal manifestations of the conservation movement. To some extent, this correlation supports the idea of land protection as an economic amenity – people value the existence of biodiversity, and its option and bequest values, more after they have achieved some base level of economic development. But a recent analysis of country-level data over time suggests that the degree of education of a populace, or the degree of freedom in a political system, is as important as the level of economic development (McDonald and Boucher, 2010).

US cities make a good case study, clearly showing the links between cities and advocacy for conservation. Teddy Roosevelt, born in wealth in Manhattan, and others in Eastern cities, played a key role in the creation of what is now Yellowstone

National Park (cf. Schullery and Whittlesey, 2003). Without citizens in San Francisco organizing into the Sierra Club, it is unlikely that Yosemite would have been protected (e.g., Cohen, 1988). Similarly, residents of New York City played a key role in the protection of the Adirondacks (Rosenzweig and Blackmar, 1998).

Dependence on Ecosystem Services

Just as cities are the center of demand for biodiversity conservation, so they are the center of demand for ecosystem services. Indeed, some of the desire for protected areas was not due to a biodiversity value, but rather a desire to protect the recreational amenity or scenic beauty of a site. Most people are in cities, so in one sense it is not surprising that aggregate cities are the center of demand for ecosystem services. However, there is a debate in the literature about whether the average urban dweller is more or less dependent on ecosystem services than the average rural dweller, and whether conservation projects that aim to maintain ecosystem services truly benefit the poor (Boerner *et al.*, 2007; Corbera *et al.*, 2007; Ferraro and Hanauer, 2011). On the one hand, most of the very poor globally are located in urban areas, and it is hard to imagine someone more dependent on ecosystem services than a substance farmer. On the other hand, cities are very dependent on a flow of ecosystem services to survive; most urban dwellers have little capacity to raise their own food, for example, and are dependent on someone else growing the food.

To be a true ecosystem service, a desirable ecosystem process has to occur near consumers of that service (McDonald, 2009). The degree to which proximity is essential – the transportability of an ecosystem service – varies from service to service. Furthermore, most cities have a sharp gradient in population density with a relatively dense city core and then a decline in density as one heads away from the core. These two factors lead to a gradient in ecosystem service demand gradient that varies in steepness depending on the ecosystem service. The extent to which some ecosystem process is important to urban dwellers increases with more people nearby and with greater transportability of an ecosystem service.

An example of an ecosystem service that must be supplied extremely close to people is the shade from trees. Centuries of urban planning have traditionally created tree-lined boulevards in many cities. Shade has taken on greater quantitative importance in terms of a city's energy consumption with the rise of electromechanical heating and cooling of homes. One tree's shade, in a hot climate, can reduce annual electricity consumption by 3.6–4.8 kWh day⁻¹ if it properly shades a residence (Akbari *et al.*, 1997). Such benefits, of course, only occur if trees are near buildings, and there's the rub. In many cases, those who benefit from the shade, whether individual homeowners or electric utilities, do not control what is planted on the streetscape, the domain of municipal authorities.

A slightly less local ecosystem is open space for use in recreation. Many studies looking at people's use of parks show that for day-to-day recreational opportunities, parks need to be within about a kilometer of the home (Giles-Corti *et al.*, 2005). Less frequent trips on weekends may be made within a short trip of 30 min to an hour in duration. In many cities, there is an expectation that municipal authorities will supply

recreational opportunities as a public good. In the US, this has led many cities to pass municipal bonds worth millions of dollars to protect open space.

Urban residents, of course, need water for their daily activities, and essential services like disposal of human wastes is impossible without some water. Typically the urban water source is relatively nearby the city, in the same watershed, although where necessary, cities have moved water hundreds of kilometers (e.g., [San Francisco Public Utilities Commission, 2005](#)). In many cases, natural vegetation filters water on the way to a reservoir, increasing water quality, or promotes groundwater infiltration, increasing water quantity (cf. [Dudgeon et al., 2006](#)). The value of these ecosystem services may be partially expressed through the protection or restoration of such vegetation by municipal water planners. In other cases, however, planners may be unaware of their cities' dependence on functioning ecosystem processes.

At an even broader regional or continental scale, cities are dependent on how vegetation mitigates the effect of air pollution and ensures urban residents access to clean air to breathe. The "ecosystem service" shed, or area of importance for ecosystem service provision, varies depending on micro-climatology, particularly the prevailing winds and vertical patterns of atmospheric circulation. It also depends on the pollutant; for some, like particulate matter, natural vegetation can act as a filter, while for others like low-level ozone, vegetation can actually increase pollutant formation. In general, very few mechanisms exist for valuing this ecosystem service. Most often, air pollution is controlled by restrictions on where and how it is emitted.

At the end of the spectrum of spatial scale lies climate regulation. Since greenhouse gases are well mixed in the atmosphere, carbon sequestration or avoided emissions services provided by vegetation are of service to urban dwellers regardless of where that vegetation is located. Right now, the lack of a coherent international agreement to replace the Kyoto Protocol has depressed the economic incentives for carbon sequestration or avoided emissions. Nevertheless, some cities have set ambitious targets like New York City's goal to plant a million new trees.

Land protection and other conservation activities can restore or enhance ecosystem services for urban residents. The "what" defines the "where": because of different transportability, what ecosystem service is to be conserved affects where conservation actions can be contemplated. Strictly from the perspective of demand for ecosystem services, it is usually better to be near the urban core, where there are lots of people ([Figure 5](#)). But stewardship, maintaining ecosystem processes on a preserved parcel, may be more difficult with lots of people nearby. All of the negative impacts of urban areas on ecosystem service provision noted above make the life of land stewards harder ([McDonald, 2009](#)).

It is also very expensive to purchase land or otherwise do conservation near a city center ([McDonald, 2009](#)). Cities have a sharp urban rent gradient ([Figure 5](#)), with land in the center being many times more valuable than land in the countryside. Thus, based on the ecosystem service demand gradient and the urban rent gradient, optimum placed for conservation of a particular ecosystem service varies depending on its transportability. Generally, conservationists should go as far out from a

Figure 5 Framework for thinking about ecosystem service conservation and cities. Top panel: Hypothetical decline in the value of an ecosystem service that has some transport cost with distance from city center, compared with an urban rent gradient. Note that the maximum value for a conservation action to preserve the ecosystem service will occur when the tangent to the rent curve parallels the tangent to the ecosystem service curve. Bottom panel: The net value of a conservation action to preserve an ecosystem service as a function of distance from city center, for three hypothetical ecosystem services. Note that the curve for recreational value is derived from the curves in the top panel. Adapted from McDonald RI, Forman RTT, Kareiva P, Neugarten R, Salzer D, and Fisher J (2009) Urban effects, distance, and protected areas in an urbanizing world. *Landscape and Urban Planning* 93: 63–75.

city as possible while doing ecosystem service protection, but no farther transportability is allowed. For instance, supply shade trees next to people's houses, and plant trees for carbon sequestration on very cheap land far from the city center.

Solutions

In this last section, the author discusses potential solutions to the issues discussed above. Some of these solutions aim to reduce the impact of cities on the environment, preventing or mitigating damage. Other solutions seek to enhance or at least maintain the flow of ecosystem services for urban residents. In the first subsection, we look at how urban form can make a city more or less sustainable. Next, we look at efforts to "mainstream" ecosystem services, putting them into everyday

decision-making. Finally, we discuss how urbanization can lead to lower population growth and rates of habitat conversion in the countryside.

Shaping More Sustainable Cities

Above, we discussed how the shape of a city controls its impact on natural habitat. Reductions in urban areas will generally reduce the amount of natural habitat lost during development, while more spatial contiguity of urban development will limit edge and isolation effects from habitat fragmentation (Seto *et al.*, 2010). The urban form of a city also mediates how people live and work, affecting the overall environmental footprint of a city. The urban form thus controls a city's environmental impact, but over the long term is also shaped by the environment, both in terms of the physical landscape (e.g., topography) and in terms of the city's dependence on ecosystem services. Other factors important in determining urban form include mode of transit, public policy, and zoning. Most importantly, urban form also has cultural dimensions, as esthetics and a people's sense of priorities can shape urban form profoundly.

One of the most commonly advocated ways to make cities more sustainable is to make them more compact. Compact city theory postulates that cities that are more dense and less fragmented have lower per capita use of many natural resources, less per capita pollution, and promote a psychologically and socially healthier environment for urbanites (Alberti, 2005; Leichenko and Solecki, 2005). For instance, average vehicle kilometers traveled (VKT) is well predicted by average population in cities in the developed world

(Kenworthy *et al.*, 1992; Newman *et al.*, 1992; Kenworthy and Laube, 1999), wherein cities with densities lower than 30 people ha⁻¹ have significantly more VKT per capita (Figure 6). More dense cities tend to use less energy for heating, cooling, and lighting than less dense cities, primarily because there are significant economies of scale by sharing space in one building rather than having multiple buildings (Steemers, 2003; Holden and Norland, 2005). Of course, the smaller amount of urban area implied by a compact city has obvious habitat conservation benefits, and indeed it is suburban or exurban

Figure 7 Conceptual graph of the additional provision of an ecosystem service after a conservation action, measured above a baseline (i.e., what would have occurred without the conservation action).

Figure 6 Correlation between population density and vehicle kilometers traveled (VKT) for a sample of cities in developed countries. For reference, the two most extreme cities in this sample are labeled on the graph. Data taken from Kenworthy J and Laube F (2000) *An International Sourcebook of Automobile Dependence in Cities, 1960–1990*. Boulder: University of Colorado Press.

sprawl (settlements at the edge of cities at very low density) that is the biggest habitat conversion threat in many cities (Theobald, 2001). And it is often argued, particularly by those of the “New Urbanist” school of planning, that more compact cities are better for creating walkable neighborhoods and a sense of social cohesion (e.g., Duany *et al.*, 2000).

In all modern cities, zoning plays a significant role in shaping urban form (Jackson, 1985). Originally, zoning was about segregating industrial land-uses from the residential ones for public health reasons. However, zoning has become a complex set of rules that perform a huge variety of functions, from preventing development at high densities (so-called exclusionary zoning) to controlling signs that landowners can post. There has been a movement away from strictly separating land uses toward multiuse zoning that is more compatible with the compact city theory discussed above. Still, the overall effect of zoning in the US is to guarantee that new developments have relatively low population density, as neighborhoods seek to restrain developers and maintain their current character (Pendall *et al.*, 2006). Current residents benefit from the maintenance of the status quo, while future potential residents are kept out. Zoning has thus arguably led to greater urban sprawl, at least in the US, and hence greater environmental impact.

Cities (or neighborhoods in cities) that developed after the widespread availability of the automobile have a very different urban form than those that were developed before (Jackson, 1985). Automobile-dependent areas are typically at a lower density, and have less of a central business district and more dispersed business parks. However, public policy toward automobiles and mass transit varies from one jurisdiction to another, with discernable effects on urban form. Note that all countries subsidize both road construction and mass transit infrastructure, often from general tax revenue but sometimes from gas taxes or user fees, but some countries spend a greater proportion of subsidies on automobiles (e.g., US), while other spend a greater proportion on mass transit (e.g., Japan). Generally, investment in mass transit leads to a more compact city, with all of its environmental benefits, while investment in roads leads to a more dispersed city.

Mainstreaming Ecosystem Services

As discussed above (*see* Effects of Cities on the Environment), most urban decision-makers face a profoundly dysfunctional incentive structure, where their dependence on ecosystem services is ignored and their impact on ecosystem services for others little considered. One hope of environmentalists is that by incorporating ecosystem services into urban decision-making, better environmental outcomes will be reached. This could be through a direct payment for the ecosystem services from beneficiary to provider, where according to economic theory the market transaction will increase overall welfare for

the two participants (Kolstad, 2000). More commonly, public policy incentives are used to create actions that maintain or enhance ecosystem services. For instance, city ordinances that encourage using drought tolerant plants in gardens are, in a sense, protecting freshwater resources by minimizing human withdrawals for landscape irrigation.

The spatial scale at which a market or incentives must operate depends on the transportability of the ecosystem service (McDonald, 2009). It also depends on administrative or political boundaries. While these boundaries are usually drawn without regard to ecological boundaries such as watersheds, they nevertheless often define the administrative area that might pay for a service or help provide. Finally, any ecosystem service market or incentive must exist in a specific cultural context, which controls what forms the market or incentive can practically take. For instance, in much of the Western world the concept of private property is widely accepted, and so it is a small intellectual step to think about private water-use rights or grazing rights. However, in many traditional pastoral systems, such as in Mongolia, most land is considered the common property of all, making notions of an ecosystem service market in the strict sense more problematic.

As an example of how an ecosystem service market or incentive might work in a city, consider shade trees and the important climate regulation they provide, significantly reducing heating and cooling costs. As discussed above (*see* Effects of Cities on the Environment), there is a disconnect between the beneficiaries of this service (homeowners and especially electric utilities) and those who plant and maintain landscaping (often building managers or municipal governments). Picture an electric utility offering to pay a set fee to municipal government for each tree it plants that provides useful shade, perhaps with restrictions on the orientation of the site, proximity to a building, and type of tree species involved so as to ensure the needed shade is truly provided. The utility is expressing how much they value the service by the price they offer to pay, and the municipality is expressing how much it costs to plant and maintain trees by the number of trees they plant at that price.

One can imagine a set of problems that might (and do!) occur when trying to set up an ecosystem service market or incentive like this (Brown *et al.*, 2007). There are very real transaction costs in negotiating and monitoring a deal between ecosystem service beneficiaries and providers. This is particularly true when there are multiple individual actors in either group, which poses a coordination and group action problem. Another potential hurdle ecosystem services schemes must jump is how to accurately, yet tractably, measure the quantity of an ecosystem service provided by an action. For instance, how much does any particular shade tree reduce cooling bills, and how can one cheaply yet relatively and accurately estimate that quantity? Specifically, one must measure the quantity of an ecosystem service provided relative to some baseline (Figure 7), the amount of ecosystem service provision

Figure 8 Geography of population decline and population increase. Top panel: Increase in population from 1995 to 2005, from the Gridded Population of the World database (CIESIN & CIAT, 2005). This dataset incorporates information from population censuses at the subnational scale, and includes information on both rural and urban populations, but because of the spatial aggregation of urban populations the observed pattern is largely due to changes in rural population. Bottom panel: National-level forecasts for the increase in rural population from 2010 to 2030, from the World Urbanization Prospects database (UNPD, 2009).

that would have occurred without any additional action. Related to this, one must also ensure that any increase in ecosystem service provision in one place does not cause actions at another site that reduces ecosystem service provision, a phenomenon termed “leakage” (e.g., Kindermann *et al.*, 2008).

A more regional example of an ecosystem service scheme might be water funds (Tallis *et al.*, 2009). In a water fund, users of water (often a water utility) set aside money that funds conservation actions upstream of the reservoir that increases water quantity or quality. For example, in Quito, the main water utility has set aside money for land protection and the construction of riparian buffer strips upstream in the paramo. These water funds have generally been easiest to set up when there is a single beneficiary and only a few land-owners or land management agencies control a large area upstream. Note that the conservation strategies required to improve water quality, generally reduction in erosion of excess N and P run-off, are quite different than those required to increase water quantity, generally making agricultural irrigation more efficient or changing land cover to one that has lower evapotranspiration.

Finally, climate change furnishes a good global example of an ecosystem service market. Any project that reduces emissions or increases carbon sequestration results in a global benefit, but the cost of performing the project is borne at the site. The idea behind things like the Clean Development Mechanism and the Voluntary Carbon Standard is to pay local providers for providing a global benefit. However, a qualifying “project” could be interpreted much more broadly for cities than is currently done in the market for carbon offsets, leading in the limit to what you could call payment for sustainable urbanization (McDonald, 2008). For instance, a project to create a new subway system in a poor, rapidly growing city arguably might have global carbon value if, after accounting for baseline and leakage, a city is polluting less because fewer people drive.

New Opportunities in the Countryside

Rural-to-urban migration may reduce population growth in some rural areas significantly, and in some regions may lead to an actual decline in population (Figure 8). This potentially provides new opportunities for conservation. The reduced development pressure in rural areas means remaining natural areas can be more easily protected, and if agricultural land is abandoned, restoration may be a possibility. Areas with an absolute decline in population over the period 1995–2005 include much of Eastern Europe and the former Soviet Union, as well as portions of Mexico and China. Forecast patterns for the next 20 years look similar, with other countries in Southeast Asia beginning to lose rural population as well. However, in practice, most developing countries with substantial rural-to-urban migration still have large population growth rate in rural areas, limiting the importance of this “rewilding” opportunity (Boerner *et al.*, 2007; Corbera *et al.*, 2007; Ferraro and Hanauer, 2011). This is particularly true for Sub-Saharan Africa and South-Central Asia, which see quite striking increases in rural population over the same time period.

In Situ, Ex Situ Conservation

Nigel Maxted, University of Birmingham, Birmingham, UK

© 2013 Elsevier Inc. All rights reserved.

Glossary

Complementary conservation Application of a range of conservation techniques (including *ex situ* and *in situ*) to conserve the target taxon, one technique acting as a backup to another. The degree of emphasis placed on each technique depends on the conservation aims, the type of species being conserved, the resources available, and whether the species has utilization potential.

Conservation Maintenance of the diversity of living organisms, their habitats, and the interrelationships among organisms and their environment.

Ecogeography Analysis of a species' ecological, geographical, and taxonomic characteristics to assist in the formulation of collection and conservation priorities.

Effective population size (N_e) Number of conserved individuals that would undergo the same amount of random genetic drift as the actual population.

Ex situ conservation Conservation of the components of biological diversity outside their natural habitats.

Gap analysis Formalized analysis of a species' ecological, geographical, and taxonomic range compared with that currently sampled for active conservation to identify 'gaps' and therefore future conservation priorities.

Gene pool The total genetic diversity found within an individual species or species group.

Genetic erosion Loss of genetic diversity from a species, often caused by anthropogenic factors.

In situ conservation Conservation of ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings and, in the case of domesticates or cultivated species, in the surroundings where they have developed their distinctive properties.

Keystone species Usually the dominant species within a habitat that tend to define it physiognomically and ecologically, for example, by determining nutrient and water cycling.

Introduction

The conservation of biodiversity is of critical importance, first because that diversity is under threat of extinction and erosion, but second because that diversity can be of direct and indirect benefit to humankind and is vital for human well-being. Biodiversity benefits humans through the exploitation of animals and plants in agriculture and horticulture, the development of medicinal drugs, and the pivotal roles played by species in the functioning of all natural ecosystems. Biodiversity is also valuable for ethical, esthetic, and recreational reasons. The fundamental importance of these issues to humankind was paramount at the United Nations Conference on the Environment and Development (UNCED) held in Rio de Janeiro, Brazil, in 1992. The Convention on Biological Diversity (CBD), which has subsequently been ratified by 168 countries (as of March, 2012), has as its objectives

the conservation of biological diversity, the sustainable use of its components and the fair and equitable sharing of the benefits arising out of the utilisation of genetic resources. (Article 1: Objectives; [Convention on Biological Diversity, 1992](#)).

More recently the CBD (2010) has established the Strategic Plan for Biodiversity 2011–2020, including the 20 Aichi Biodiversity Targets, that aim to address the underlying causes of biodiversity loss, reduce the direct pressures on biodiversity and promote sustainable use, improve the status of biodiversity by safeguarding ecosystems, species and genetic diversity, enhance

the benefits to all from biodiversity and ecosystem services and also enhance implementation through participatory planning, knowledge management, and capacity building.

Why Does Biodiversity Need Conservation?

Estimates of the total number of species in the world vary, but approximately 1.75 million species have been scientifically described out of an estimated 14 million species ([Groombridge and Jenkins, 2002](#)). It is difficult to estimate rates of species extinction, but the consensus view summarized by [Lugo \(1988\)](#) was that 15–20% of all species could become extinct by the turn of the century. It is even more difficult, if not impossible, to estimate precise levels of genetic erosion, that is, the loss of genetic diversity from extant species. However, the loss of genetic diversity must always be faster than the loss of species because there will be some genetic erosion from the species that remain extant. Loss of any genetic diversity means that the affected plants or animals will not be able to adapt to changing conditions quite so readily; for example, potato cultivars with a narrow genetic base were unable to withstand the infection of late potato blight (*Phytophthora infestans*) in the late 1840s in Ireland, the crop was devastated, and millions were forced to emigrate or starve. Although genetic erosion cannot be quantified accurately, it seems likely that virtually all species are currently suffering loss of genetic variation to varying degrees. Therefore, using Lugo's figures as a starting point, it may be estimated that 25–35% of plant and

animal genetic diversity could possibly be lost over the 12-year period leading up to the year 2000 (Maxted *et al.*, 1997a).

Of course, loss of biodiversity also occurs at other levels than species, for habitats and ecological communities can also be degraded or destroyed. For example, virtually all of the natural grasslands in the USA have been lost since 1942 (Spellerberg, 1996), over 90% of natural wetlands in New Zealand have been lost since European settlement, and Fernside (1990) estimated that world forest loss was proceeding at 20,000 km² per year. In a similar study, FAO and UNEP (1991) found that annual rates of forest loss had increased from 113,000 km² to 169,000 km² per year between 1980 and 1990 in 76 countries. However, a more recent assessment between 2000 and 2010 found the rate of loss had slowed to 130,000 km² per year (FAO, 2011).

It is important to realize, however, that both species extinction and genetic erosion can be natural events, just as species and genetic evolution are natural; nature is and it seems has always been dynamic. Yet the current levels of species extinction and genetic erosion are dramatically higher than the so-called background levels that existed hundreds, thousands, and millions of years ago. Humankind now has the capacity to drastically alter the world environment in ways that were not previously possible, and these anthropogenic changes are undoubtedly increasing the rates of species and genetic extinction.

What Threatens Biodiversity?

The threat to biodiversity as a result of anthropogenic changes is not universal for all species. Some species are in greater danger of genetic erosion (or even of complete extinction) than others. These dangers must be evaluated carefully, so that those exposed to the highest risk can be given higher priority for conservation. However, it must also be borne in mind that levels of threat often change rapidly and unexpectedly. Thus, an area may suddenly come under the threat of industrial

development, road-building, or logging. The kind of events that lead to genetic erosion or even extinction may be broadly grouped under the general headings of

- destruction, degradation, and fragmentation of natural habitats;
- overexploitation and incidental take;
- introduction of exotic species that compete with, prey on, or hybridize with native species;
- human socioeconomic change and upheaval;
- changes in agricultural practices and land use;
- calamities, both natural and man-made.

But today the greatest potential threat to biodiversity is climate change, even if its precise quantification is still a matter of debate (IPCC, 2007).

It is valuable to establish a system by which the relative threat of genetic erosion can be assessed objectively. Guarino (1995) proposed a model for estimating the threat of genetic erosion that a taxon (wild or cultivated) faces in a particular region. The model may be used without having to visit the region involved, provided some background data are available on the taxon and the area. The model is based on scoring a number of parameters, such as the abundance of the taxon, the level of agricultural development, and the proximity and intensity of various types of human activity to the populations being studied. The higher the score, the greater the risk of genetic erosion and therefore the higher priority for *in situ* or *ex situ* conservation.

The International Union for Conservation of Nature and Natural Resources (IUCN, now known as the World Conservation Union) has developed a system of categories of conservation status, which is based on detailed knowledge of the population dynamics and characteristics of the species concerned, the so-called IUCN Red Data List Categories (IUCN, 2001) (Figure 1). Using these categories, for example, a 'Critically Endangered' species would be assigned higher conservation priority than a 'Vulnerable' species. However, IUCN has tended to focus their attention almost exclusively

Figure 1 Structure of the IUCN categories of threat. Reproduced from IUCN (2001) *IUCN Red List Categories, Version 3.1*. Gland, Switzerland: IUCN Species Survival Commission.

on species extinction rather than genetic erosion within individual gene pools, and the latter may be of equal importance in terms of overall loss of biodiversity.

What Is Biodiversity Conservation?

Spellerberg and Hargis (1992) stated that biodiversity conservation aims to “maintain the diversity of living organisms, their habitats and the interrelationships between organisms and their environment.” But how is this to be achieved?

Conservationists must clearly define and understand the processes involved, and then attempt to develop practical techniques to achieve this objective. When undertaking a particular conservation exercise, a conservationist must use his or her knowledge of genetics, ecology, geography, taxonomy, and many other disciplines to understand and manage the biodiversity that is being conserved.

It is important to stress that conservation is not just about individual plant and animal species, but also includes all aspects of biodiversity from ecosystems (a community of organisms and its abiotic environment), through communities (a collection of species found in a common environment or habitat), species, and populations, to genetic diversity within species. In recent years there has been a differentiation between conservation at the ecosystem and at the genetic levels, and these may be referred to as ecological and genetic conservation, respectively.

Ecological conservation focuses on the conservation of whole communities; although the survival of individuals and the extinction of particular species are a major concern, both are viewed in the larger context of overall community health. This form of whole-community conservation is exemplified by the ‘Man and the Biosphere’ program (UNESCO, 1996), which established a network of biosphere reserves representing distinct biomes and ecosystems throughout the world. The clear emphasis was on conservation of ecosystems: this program believed that individual species should be conserved as a component of ecosystems rather than on a species-by-species basis.

Genetic conservation focuses more explicitly on particular taxa and attempts to conserve the full range of genetic (allelic) variation within those taxa. The aim of this form of conservation is often utilitarian, for genetic diversity conservation is often linked intimately to human utilization. However, Maxted *et al.* (1997b) stressed the following points: first, species usefulness does not have to be defined in the strictest utilitarian sense, because plants and animals considered of esthetic value are equally worthy of receiving human value as those of immediate use to plant or animal breeders; and second, in many cases individual species cannot be conserved without conserving the communities in which they naturally occur. So the distinction between the two basic forms of conservation is in practice blurred and may be viewed as artificial and of limited semantic importance, because the conservation of ecosystems, species and their genetic diversity are intimately linked. Just as it is difficult to focus conservation effort on the generality of the entire ecosystem, in practice conservationists need to focus on something more tangible that can be monitored and managed, even if only as an exemplar for the ecosystem as a whole.

So to undertake effective conservation, species interactions must be understood as far as possible. Even if the conservation target is a population of a single species, no populations survive in isolation. They exist within a community or ecosystem and interact with other species and the abiotic environment. Obvious examples of interactions include pollinators, seed dispersers, microbial symbionts, herbivores (whether natural or introduced by humans), predators, and pathogens. Thus, even when applying genetic *in situ* conservation, the maintenance of genetic diversity will have to be considered within the context of whole-ecosystem conservation.

The so-called keystone species are important in this context, for these species contribute significantly to the structure of a community or its processes; they are the dominant species. The removal of a keystone species renders other members of a community vulnerable to extinction. Tropical trees that produce a rich food resource in the form of fruit or seeds, for example, can be considered keystone species, as they provide a vital food source for a diverse array of mammals and birds. Generally keystone species play an important part in interactions between different trophic levels, whether they are predators, herbivores, mutualists such as pollinators, or decomposers. So when considering the conservation of any particular species within an ecosystem, one must identify the inherent interactions and ensure their maintenance if the conservation project is to be successful and sustainable.

Methods of Conservation

There is a need to develop appropriate methodologies for biodiversity conservation, particularly in the tropics. The tropical regions of the world have the highest levels of biodiversity, but their fauna and flora are the least well known and are most under threat. Also, tropical nations have few conservationists and often they are insufficiently trained; furthermore, the resources available for conservation activities are relatively limited. To address these issues, the CBD asks nations to:

Promote and encourage research that contributes to the conservation and sustainable use of biological diversity, particularly in developing countries. (Article 12; CBD, 1992)

Maxted *et al.* (1997b) responded to this requirement – to clarify and enhance the methodologies and research programs that currently enable scientists to classify, conserve, manage, and utilize biodiversity – by proposing a model for plant and animal genetic diversity conservation (Figure 2). The raw materials of genetic conservation are genes within gene pools, which represent the total diversity of genetic material of the particular taxon being conserved. The product of the gene pool (seeds, eggs, ovules, etc.) is either preserved or utilized as genetic diversity. The processes that link the raw matter and the utilized gene pool represent genetic conservation.

Selection of Target Taxa

Conservation activities will always be limited by the financial, temporal, and technical resources available. Conservation of ecosystems or species has a cost and the effort expended is directly related to how much society values that species and is

Figure 2 Model of biodiversity conservation. Adapted from Maxted N, Ford-Lloyd BV, and Hawkes JG (1997b) *Plant Genetic Conservation: The In Situ Approach*. London: Chapman & Hall.

therefore willing to pay. It is impossible to actively conserve or monitor all species, so it is important to make the most efficient and effective selection of species on which to focus conservation efforts. This choice should be objective and based on logical, scientific, and economic principles related to the perceived value of the species. Maxted *et al.* (1997a) discussed the sort of factors that provide a species with 'value': current

conservation status, potential economic use, threat of genetic erosion, genetic distinction, ecogeographic distinction, national or conservation agency priorities, biological importance, cultural importance, relative cost of conservation, conservation sustainability, and ethical and esthetic considerations.

Rarely will one of these factors on its own lead to a taxon being given conservation priority. More commonly, all or a

range of these factors will be assessed for a particular taxon and then it will be given a certain level of national, regional, or world conservation priority. If the overall score passes a threshold level or is higher than those of competing taxa, the taxon will be conserved; it will then be either collected and conserved *ex situ*, an appropriate reserve will be established, or on-farm conservation will be proposed. Having listed the factors that affect the selection of target taxa in terms of value to society, those related to potential economic use will commonly be given higher comparative value, especially in economically poorer economies where income generation is of the highest priority. This anthropocentric and utilitarian view in the selection of conservation priorities may offend some conservationists, but when financial resources for conservation are, and are likely to remain, limited, and when men, women, and children are still suffering from malnutrition in many parts of the world, there appears to be no practical or ethical alternative to giving those species of most direct use to people the highest value and thus the highest conservation priority.

Project Commission

In practice, once taxa are selected for conservation, the actual conservation activities are necessarily preceded by some form of commission statement. This is likely to establish the objectives of the conservation, specify the target taxa and target areas, state how the material is to be utilized and where the conserved material is to be safely duplicated, and perhaps indicate which conservation techniques are to be employed. A clear, concise commission statement will help to focus subsequent conservation activities.

Who writes the commission? The commission statement may be written by those contracting the conservation or those who actually undertake the conservation work. The commission may vary in taxonomic and geographic coverage, from a systematic collection program for a single species throughout its geographic range to a range of target taxa from a restricted location, for example, onion (*Allium*) species of Central Asia, large cat species worldwide, or chickpeas (*Cicer*) from the Western Tien Shen. In each case, however, a particular group of taxa from a defined geographical area must be considered to be insufficiently conserved (either *in situ* or *ex situ*), of sufficient actual or potential use, or endangered to warrant active conservation.

Ecogeographic Survey, Gap Analysis, and Preliminary Survey Mission

Once the target taxon or group of taxa have been selected and delimited, the conservationist begins to amass and synthesize fundamental biological data to help formulate an appropriate conservation strategy. The synthesis and analysis of these data enable the conservationist to make vital decisions concerning, for example, which taxa to be included in the target group, where to find these taxa, which combination of *ex situ* and *in situ* conservation to use, what sampling strategy to adopt, where to store the germplasm and site the reserve or what captive breeding program would be most successful. If the

basic biological data for a particular species, for example, the close lentil relative *Lens culinaris* subsp. *orientalis*, indicate that the species has been previously found on stony slopes at the edge of the Fergana valley in Uzbekistan, then further material of this species is likely to be currently found under similar constraints and is less likely to be found in different habitat types or in far distant regions.

The process of collating and analyzing geographical, ecological, and taxonomic data for use in designing conservation strategies is referred to as ecogeography and was defined by Maxted *et al.* (1995) as:

an ecological, geographical and taxonomic information gathering and synthesis process for a particular taxon. The results are predictive and can be used to assist in the formulation of collection and conservation priorities.

Ecogeographic studies involve the use of large and complex data sets obtained from the literature and from the compilation of passport data associated with herbarium specimens and germplasm accessions. These data are synthesized to produce three basic products: the database, which contains the raw data for each taxon; the conspectus, which summarizes the data for each taxon; and the report, which discusses the contents of the database and conspectus, as well as proposing appropriate conservation strategies. Ecogeographic techniques enhance the efficiency of crop relative and wild species conservation because they enable the conservationist to identify clearly the geographical regions and ecological niches that the taxon inhabits, and so not only identify areas with high numbers of target taxa, but also areas that contain high taxonomic or genotypic diversity of taxa, uniqueness of habitat, economic or breeding importance, and so on.

The ecogeographic study may form part of a more formulated gap analysis, which originally was used in a more limited sense to identify areas in which selected elements of biodiversity are under-represented (indigenous forests, particularly on small islands rich in endemic species) (see Margules, 1989; Balmford, 2003), but the methodology can be adapted for more general species conservation use (Maxted *et al.*, 2008) involving four steps: (1) identification of priority taxa, (2) identification of the ecogeographic breadth and complementary target taxon hotspots using genetic diversity, distribution, and environmental data, (3) match current *in situ* and *ex situ* conservation actions with the identified genetic diversity, ecogeographic breadth and complementary species hotspots to identify the so-called conservation 'gaps,' and so (4) formulate a revised *in situ* and *ex situ* conservation strategy for the target taxon. Gap analysis has rapidly established itself as the methodology for species conservation planning.

If the available ecogeographic data for the target taxon are limited, whether undertaking an ecogeographic survey or gap analysis the conservationist will not have sufficient background biological knowledge to formulate an effective conservation strategy. In this case it would be necessary to undertake an initial survey mission to gather the novel ecogeographic data required on which to base the actual conservation strategy. The survey mission may be in the form of 'coarse grid sampling' which involves traveling throughout a likely target region and sampling sites at relatively wide intervals over the whole region. The precise size of the interval between sites depends on the level of environmental diversity

across the region, but it may involve sampling every 1–50 km. The population samples and data collected during this mission can then be used to formulate further conservation priorities and to develop an appropriate strategy, thus providing the same result as the ecogeographic survey for groups that are better biologically understood.

Conservation Objectives

The products of the ecogeographic survey, gap analysis, or survey mission provide a basis for the conservationist to formulate future conservation priorities and strategies for the target taxon. Within the target area, zones of particular interest may be identified, for example, areas with high concentrations of diverse taxa, low or very high rainfall, or high frequency of saline soils or extremes of altitude or exposure. In general, areas with very distinctive characteristics are likely to contain plants with distinct genes or genotypes. If a taxon is found throughout a particular region, then the researcher can use the ecogeographic data to positively select a series of diverse habitats to designate as reserves. If a taxon has been found at one location but not at another with similar ecogeographic conditions, then the conservationist may suggest that these similar locations should be searched. Within the target taxon, specific variants may be identified that warrant conservation priority, for example, species that have previously unrecognized utilization potential, populations that are particularly in danger of genetic erosion, or those that had not previously been conserved.

The conservationist must set out a clear, concise statement of the proposed conservation strategy for the target taxon and, if appropriate, prioritize actions. These may have been established in the project commission, but if not the conservationist should undertake the task. This should answer questions such as: Which populations require conservation? Can local farmers play a part in conservation activities? Do population levels require close monitoring? Should a national or international collecting team be directed to collect the priority target taxa? What conservation strategy or strategies are appropriate? What combination of conservation techniques is appropriate or is a more detailed study required before any of these questions can be answered?

Field Exploration

Once the conservation objectives have been clarified, whichever conservation strategy is to be applied, the ecogeographic information is used to locate and identify the general locality of the animal or plant populations that are to be conserved. The ecogeographic data will rarely be sufficiently comprehensive to precisely locate actual populations. Therefore, the preparatory element of conservation activities will be followed by field exploration, during which actual populations are located. Ideally, populations of the target taxon that contain the maximum amount of genetic diversity in the minimum number of populations will be identified, but how is this goal to be achieved? Commonly there will be too much diversity in both crops and wild species to conserve all their alleles, even if these were known then or at some future time.

Thus the conservationist must attempt to conserve the range of diversity that best reflects the total genetic diversity of the species. How many animals or plants must be sampled, which specimens and what pattern of sampling is appropriate? To answer these specific questions the conservationist should know the amount of genetic variation within and between populations, local population structure, the breeding system, taxonomy and ecogeographic requirements of the target taxon, and many other biological details. Some of this information will be supplied following the ecogeographic survey, but some will remain unavailable. Therefore, the practice of field exploration will be modified depending on the biological information on the target taxon and target area that is available.

For a botanical project, the field botanist should select populations if they are found on the periphery of the target taxon's distribution or those that contain morphological or ecological variants. Atypical populations or those growing under atypical conditions may possess genes or alleles that are unknown or extremely rare in the target taxon's center of diversity, and this material possibly contains genetic variation that is of special use to breeders (e.g., disease or pest resistance or adaptation to soil or climate that is unknown in the crop itself).

Conservation Strategies

There are two basic conservation strategies, each composed of various techniques, that the conservationist can adopt to conserve genetic diversity once it has been located. The two strategies are *ex situ* and *in situ* conservation. Article 2 of the CBD (1992) provides the following definition of these categories:

In situ conservation means the conservation of ecosystems and natural habitats and the maintenance and recovery of viable populations of species in their natural surroundings and, in the case of domesticates or cultivated species, in the surroundings where they have developed their distinctive properties.

Ex situ conservation means the conservation of components of biological diversity outside their natural habitats.
